Random walks and graphs

a few topics
(preliminary version)

N.C.

February 5, 2019
This is the current draft of the lecture notes for the Master 2 course “Marches et graphes aléatoires” given during the years 2016-2019 at université d’Orsay. Thanks are due to the students of this course for having tested this material in particular to Maxime Berger, Jacques De Catelan, Barbara Dembin, Alejandro Fernandez and Corentin Morandeau (promotion 2016) Chenlin Gu, Enzo Miller, Arthur Blanc-Renaudie, Kévin Marchand, Rémy Mahfouf (promotion 2017) Antoine Picard-Weibel (promotion 2018). Additional materials and complements may be found in [8, 10, 13, 14, 17, 19]. Remarks, comments and list of typos are very much welcome at this stage!!!

They are many wonderful books about random walks ([24, 25, 14, 2] just to name a few) and these lecture notes instead of seeking exhaustivity should rather be taken as a pretext to present nice probabilistic techniques and geometric concepts (potential theory, rough isometries, cyclic lemma, second moment method, stable random variables, large deviations estimations, size-biasing, coding of trees via paths, probabilistic enumeration, Fourier transform, coupling, recursive distributional equation, local limit theorems, local convergence...) in a master course.

Part I:

Electrical networks

In this part we study general random walks on (weighted, finite or infinite) graphs. We related this object to the theory of electrical networks by interpreting the return probabilities for the walk as potential for the associated electrical networks. In particular we give equivalent characterization of recurrence/transience of a graph in terms of resistance to infinity. This enables us to give robust criteria for recurrence/transience on infinite graphs. We also introduce the discrete Gaussian free field and connect it to potential theory. We refer to [19, Chapter 2] (and its 139 additional exercises!) for more details and to [9] for a smooth introduction to the subject.

Figure 1: ???
Chapter I: Finite electrical networks

In this chapter we develop the well-known connection between potential theory and random walks on finite (weighted) graphs. This enables us to give a probabilistic interpretation of resistance, electric potential and electric current.

1.1 Random walks and Dirichlet problem

1.1.1 Random walk

A graph $\mathbb{g}$ is described by its set of vertices $V = V(\mathbb{g})$ and its set of edges $E = E(\mathbb{g})$ which is a multiset of pairs of (non-necessarily distinct) vertices, that is, an edge $e = \{x, y\}$ can appear several times inside $E$ and loops $\{x, x\}$ are allowed. It is useful to also consider the multiset $\tilde{E} = \tilde{E}(\mathbb{g})$ of oriented edges obtained by splitting every edge $\{x, y\}$ of $E$ into the two oriented edges $(x, y)$ and $(y, x)$. The starting point of $\tilde{e}$ is denoted by $\tilde{e}^*$ and its target is $\tilde{e}^{**}$. The degree of a vertex $x \in V$ is the number of oriented edges (counted with multiplicity) starting at $x$:

$$\deg(x) = \#\{(x, y) \in \tilde{E}(\mathbb{g})\}.$$

Figure 1.1: On the left a weighted graph. On the right the corresponding graph with oriented edges.

---

1 non-oriented multigraph to be precise
Definition 1.1 (Conductance). A conductance is a function $c : E(\mathbf{g}) \to [0, \infty]$. The conductance of an oriented edge is by definition the conductance of its associated non-oriented edge. The pair $(\mathbf{g}, x)$ is a weighted graph. The weight of a vertex $x$ is the sum of the conductance of oriented edges starting from $x$:

$$\pi(x) = \sum_{\vec{e}=(x,y)\in \vec{E}} c(\vec{e}).$$

Remark 1.1. Considering multi-graph may yield to a lack of precision in the notation, for example if the edge $\{x, y\}$ is present with a multiplicity, each of its copies may carry a different conductance. Implicitly when summing over edges we will always sum over the different copies of the edges carrying the possibly different conductances. The confused reader may assume at first reading that all the graphs considered are simple (no loops nor multiple edges) so that this problem disappears.

We write $x \sim y$ if the two vertices $x, y \in V$ share an edge of positive conductance and say that they are in the same connected component. Unless specified:

**All the graphs considered in these notes are connected and all degrees are finite.**

This notion of conductance is used in the definition of the random walk. The standard notion of random walk is a process evolving on the vertices of the graph, but we will see that sometimes it is more convenient to think of it as the trace of a process evolving on the oriented edges of the graph.

Definition 1.2 (Random walk on $(\mathbf{g}, c)$). If $(\mathbf{g}, c)$ is a weighted graph, for any $\vec{e}_0 \in \vec{E}(\mathbf{g})$, the edge-random walk started from $\vec{e}_0$ is the Markov chain $(\vec{E}_n : n \geq 0)$ with values in $\vec{E}$ whose probability transitions are given by

$$P(\vec{E}_{n+1} = \vec{e}_{n+1} \mid \vec{E}_n = \vec{e}_n) = \frac{c(\vec{e}_{n+1})}{\pi(\vec{e}_n^*)} 1_{\vec{e}_n^* = (\vec{e}_{n+1})^*}.$$

The projection of the random walk on the vertices of $\mathbf{g}$ is thus the Markov chain $(X_n : n \geq 0)$ called “random walk on $(\mathbf{g}, c)$” whose probability transitions $p$ are

$$p(x, y) = P(X_{n+1} = y \mid X_n = x) = \frac{c(x, y)}{\pi(x)},$$

where $c(x, y)$ is the sum of all the conductances of the oriented edges $(x, y) \in \vec{E}$.

Example 1.1. When the conductance function is $c \equiv 1$, the degree of a vertex (for $c$) coincides with its graph degree and the random walk $(X_n)_{n \geq 0}$ is the simple random walk on the graph $\mathbf{g}$: it chooses, independently of the past, a neighbor uniformly at random (according to the number of connections to that point) and jumps to it.

Since $(X_n)$ is a discrete time Markov \(^2\) chain with a countable state space, it enjoys the

\(^2\) Andreï Andreïevitch Markov (1856-1922)
Markov property which we now recall: If $\mathcal{F}_n$ is the filtration generated by the first $n$ steps of the walk, a stopping time is a random variable $\theta \in \{0, 1, 2, \ldots \} \cup \{\infty\}$ such that $\{\theta = n\}$ is $\mathcal{F}_n$-measurable. The $\sigma$-field $\mathcal{F}_\theta$ of the past before $\theta$ is made of those events $A$ such that $A \cap \{\theta \leq n\}$ is $\mathcal{F}_n$-measurable. The (strong) Markov property says that conditionally on $\mathcal{F}_\theta$ and on $\{\theta < \infty\}$ the law of $(X_{\theta+k} : k \geq 0)$ is $\mathbb{P}_{X_\theta}$ where we denote as usual $\mathbb{P}_x$ for the law of the Markov chain started from $x \in V$.

It is also very important to notice that the random walk $(X_n : n \geq 0)$ in fact admits $\pi(\cdot)$ as an invariant and even reversible measure (the easiest way to see this is to notice that the conductance $c(\cdot)$ is in fact an invariant and reversible measure for the edge-random walk chain $(\vec{E}_n)_{n \geq 0}$ and the statement follows by projection).

Here is a exercise to remind the reader a few basics in discrete Markov chain theory:

**Exercise 1.1.** Show that

- a reversible measure is necessarily invariant,
- if there exists a finite ($\neq 0$) invariant measure, then if the chain is irreducible, it is recurrent,
- a recurrent Markov chain admits a unique invariant measure up to multiplicative constant,
- there exist infinite connected weighted graphs (necessarily transient) for which there are two non proportional invariant measures for the random walk.

**1.1.2 Harmonic functions and the Dirichlet problem**

As we have seen above, Markov chains act on measures and leave invariant measures unchanged. In the dual version, we can consider their actions on functions where the analog of the concept of invariant measure is given by harmonic functions:

**Definition 1.3.** A function $h : V(\mathfrak{g}) \to \mathbb{R}$ is harmonic at $x$ for the random walk on $(\mathfrak{g}, c)$ if

$$h(x) = \sum_{x \in y} p(x, y) h(y) = \mathbb{E}_x[h(X_1)].$$

We simply say that $h$ is harmonic if it is harmonic at all vertices.

**Exercise 1.2.** Prove that $(h(X_n) : n \geq 0)$ is a martingale (for the filtration generated by the random walk) for the random walk on $(\mathfrak{g}, c)$ if and only if $h$ is harmonic.

The following problem amounts to find “harmonic extension” to prescribed functions. It is called the Dirichlet\(^3\) problem and pops-up in many areas of physics and mathematics.

\(^3\) Johann Peter Gustav Lejeune Dirichlet (1805-1859). His paternal grandfather was born in Richelette a small Belgium town, hence the name Lejeune Dirichlet "the young from Richelette"
**Dirichlet problem:** Let $A \subset V$ be a subset of vertices of the graph $g$ and suppose we are given a function $f_0 : V \setminus A \to \mathbb{R}$. The Dirichlet problem consists in finding a harmonic extension inside $A$, that is, a function $f$ satisfying:

- $f \equiv f_0$ on $V \setminus A$,
- $f$ is harmonic at every point $x \in A$.

**Theorem 1.1 (Dirichlet problem, finite case)**

If $A \subset V$ is finite and $f_0 : V \setminus A \to \mathbb{R}$ then the Dirichlet problem has a unique solution $f$ given by

$$f(x) = \mathbb{E}_x[f_0(X_{\tau_{A^c}})], \quad \text{where } \tau_{A^c} = \inf\{k \geq 0 : X_k \in A^c\}.$$

Since the above theorem is key in this chapter we give two proofs of it:

**Proof 1:** But our assumptions ($A$ is finite, $g$ is connected, all degrees are finite) it is clear that $\tau_{A^c} < \infty$ almost surely and since $f_0(X_{\tau_{A^c}})$ can take only finitely many values, it is bounded so that $f(x) = \mathbb{E}_x[f_0(X_{\tau_{A^c}})]$ is well-defined for every $x \in V$. Clearly, $f$ coincides with $f_0$ outside of $A$. The fact that $f$ is harmonic inside $A$ follows from the Markov property applied at time $\theta = 1$ since for $x \in A$ we have

$$f(x) = \mathbb{E}_x[f_0(X_{\tau_{A^c}})] = \mathbb{E}_x \left[ \mathbb{E}_{X_1} \left[ f_0(X_{\tau_{A^c}}) \right] \right] = \mathbb{E}_x[f(X_1)].$$

Hence $f$ is a solution to the Dirichlet problem. As for the uniqueness, consider another solution $\hat{f}$ harmonic inside $A$ and coinciding with $f_0$ on $V \setminus A$. Then by Exercise 1.2 the process $(\hat{f}(X_n) : n \geq 0)$ is a bounded martingale and so by the optional sampling theorem we must have for $x \in A$

$$\hat{f}(x) = \hat{f}(X_0) = \mathbb{E}_x \left[ \hat{f}(X_{\tau_{A^c}}) \right] =: f(x).$$

**Proof 2:** The Dirichlet problem is a linear problem with $\#A$ unknowns (the values of the function $f$ inside $A$) and $\#A$ equations (harmonicity of $f$ at all points in $A$). It can thus be written under the form $AX = B$ where $A$ is a square matrix, $X$ are the unknowns and $B$ is prescribed by the boundary conditions. Hence the existence and unicity of the Dirichlet problem reduces to show that the matrix $A$ is invertible, or in other words that the equation $AX = 0$ has at most a solution. It is easy to see that finding $X$ such that $AX = 0$ is equivalent to finding a harmonic function to the Dirichlet problem where the boundary condition is null i.e. when $f_0$ equal 0. The uniqueness of a possible solution can then be proved by the maximum principle: Let $g$ be a solution of the above problem and consider $x \in A$ such that $g$ is maximum. If $g \in V \setminus A$ then $g(x) = f_0(x) = 0$, otherwise by harmonicity of $g$ at $x$ we deduce that all neighbors of $x$ share this maximum value (equality case in the triangle inequality). By connectedness the maximal value of $g$ is attained on $\partial A$ and must be zero. Consequently $g \leq 0$ and by a similar argument we have $g \geq 0$, so $g \equiv 0$ as desired.
Exercise 1.3. (*) Is there always existence and uniqueness to the Dirichlet problem when $A$ is not necessarily finite? More specifically investigate the cases:

- show that there is always uniqueness the recurrent case,
- the existence may fall down in the case when the function $f$ is required to be positive (and $f_0 \geq 0$ as well),
- there is always existence in the general case.

1.2 Electrical networks

A (finite) network is the data formed by a finite weighted graph $(g,c)$ together with two (distinct) vertices $x_{in}$, called the source, and $x_{out}$ called the sink. To help the intuition, it is good to interpret this network as an actual (real) one where the edges have been replaced by resistors whose conductance (the inverse of the resistance) is prescribed by $c$ which is connected to a battery. Beware though: the reader should not confuse the physical intuition with mathematical statements!

![Figure 1.2: Setting of the next two sections: a (finite connected) weighted graph together with two distinguished vertices.](image)

1.2.1 Back to high school: reminder of physics laws

Let us start with the intuition and remind the reader of a few physics laws. In the above network, imagine that we impose potential difference between $x_{in}$ and $x_{out}$ by plugging the network on a battery of 1 Volt. This creates an electrical current, an electric potential and dissipates the energy of the battery. More precisely we can measure the following physical quantities/facts:

- The electrical potential in a function $v : V \to \mathbb{R}$ (defined up to addition but which we can fix to be) equal at 1 at $x_{in}$ and 0 at $x_{out}$ after the battery is plugged,
- The electrical current is a function $i : \vec{E} \to \mathbb{R}$ such that $i(\vec{e}) = -i(\vec{e})$.

---

Alessandro Giuseppe Antonio Anastasio Volta (1745-1827)
• Ohm’s law: for any oriented edge we have \(-c(\vec{e}) \cdot \nabla_{\vec{e}} v = i(\vec{e})\), where we used the notation 
\[
\nabla_{(x,y)} f = f(y) - f(x).
\]

• Flow property: for any \(x \notin \{x_{in}, x_{out}\}\) we have \(\sum_{\vec{e}=(x,\cdot)} i(\vec{e}) = 0\).

Combining Ohm’s law for the potential and the flow property of the current we deduce that \(v\) should be harmonic on \(V \setminus \{x_{in}, x_{out}\}\):

\[
0 = \sum_{\vec{e}=(x,\cdot)} i(\vec{e}) = \sum_{\vec{e}=(x,\cdot)} \frac{1}{\pi(x)} i(\vec{e}) = \sum_{y \sim x} p(x, y) (v(x) - v(y)).
\]

Similarly, the fact that the current can be seen as the “derivative” of the potential implies the cycle rule: the sum the current times the resistance along an oriented cycle \(C = (\vec{e}_0, \vec{e}_1, \ldots, \vec{e}_k)\) in the graph is equal to 0

\[
\sum_C i(\vec{e}_i)/c(\vec{e}_i) = -\sum_{\vec{e} \in C} \nabla_{\vec{e}} v = 0.
\]

In fact the potential and the current point of views are equivalent and it is easy to prove the following:

**Proposition 1.2.** Fix a network \(((g, c); x_{in}, x_{out})\). There is a bijection between potential functions \(v : V \rightarrow \mathbb{R}\) such that \(v(x_{out}) = 0\) which are harmonic on \(V \setminus \{x_{in}, x_{out}\}\) and current functions \(i : \vec{E} \rightarrow \mathbb{R}\) which are symmetric, possess the flow property at any \(x \notin \{x_{in}, x_{out}\}\) and obey the cycle rule. The bijection is simply given by

\[
v \longleftrightarrow i = \left( -c(\vec{e}) \cdot \nabla_{\vec{e}} v \right)_{\vec{e} \in \vec{E}}.
\]

Your high-school physics teacher also told you that the energy dissipated in the network by “Joule” heating has a power proportional to \(E = \frac{1}{2} \sum_{\vec{e}} i(\vec{e})^2/c(\vec{e}) = \frac{1}{2} \sum_{\vec{e}} c(\vec{e})(\nabla_{\vec{e}} v)^2\), and this will be proved useful later on.

1.2.2 Probabilistic interpretations

Let us come back to mathematics. We consider the same network \(((g, c); x_{in}, x_{out})\) as above our goal being to give a probabilistic interpretation to the functions \(v, i, \ldots\) that are “physically” built by the battery.
Potential

The easiest quantity to interpret is the potential. Indeed, if we impose a unit voltage between
the source and sink vertices of the graph and require Ohm’s law and the flow property, then by
Theorem 1.1 there is indeed a unique function $v$ satisfying $v(x_{in}) = 1$, $v(x_{out}) = 0$ and being
harmonic inside $V \setminus \{x_{in}, x_{out}\}$ it is given by:

**Proposition 1.3** (Probabilistic interpretation of the potential). If $\tau_{in}$ and $\tau_{out}$ respectively are
the hitting times of $x_{in}$ and $x_{out}$ by the random walk on $(g,c)$ then we have for any $x \in V$

$$v(x) = \mathbb{E}_x[v(X_{\tau_{in} \wedge \tau_{out}})] = \mathbb{P}_x(\tau_{in} < \tau_{out}).$$

**Remark 1.2.** Notice that if we impose different boundary conditions on the potential (e.g. by
plugging a different battery), then the new potential is obtained by an affine transformation.

**Remark 1.3.** The probabilistic interpretation of the potential suggests that electrons may behave
in the networks as random walkers, but unfortunately the physic knowledge of the author does
not permit to affirm such an assertion .... ;)

Current and effective resistance

In the real-world situation, we could measure the electric current. In our mathematic setup, we
define it from the potential:

**Definition 1.4.** The current $i$ is defined from the potential as follows: for any oriented edge we
put

$$i(\vec{e}) := -c(\vec{e}) \cdot \nabla_{\vec{e}} v = c(\vec{e}) \cdot (v(x_{out}^+) - v(x_{out}^-)).$$

By Proposition 1.2, it is automatic that $i$ is symmetric, obeys the cycle rule and the flow property.
The total flux from $x_{in}$ to $x_{out}$ is then

$$i_{total} = \sum_{\vec{e}=(x_{in},y)} i(\vec{e})$$

$$= \sum_{\vec{e}=(x_{in},y)} c(\vec{e}) \cdot (v(x_{out}^+) - v(x_{out}^-))$$

$$= \pi(x_{in}) \sum_{y \sim x_{in}} \frac{c(x_{in},y)}{\pi(x_{in})} (1 - \mathbb{P}_y(\tau_{in} < \tau_{out}))$$

$$= \pi(x_{in}) \mathbb{P}_{x_{in}}(\tau_{out} < \tau_{in}^+),$$

where $\tau_{in}^+ = \inf\{k \geq 1 : X_k = x_{in}\}$. Motivated by the real-world situation we define:

**Definition 1.5** (Effective resistance). The total current $i_{total}$ is proportional to the potential
difference $v(x_{in}) - v(x_{out})$ and the proportionality factor is called the effective conductance $C_{eff}$
of the graph $(g,c)$ between $x_{in}$ and $x_{out}$ (its inverse is the effective resistance $R_{eff}$). From the
above we have

$$C_{eff} = C_{eff}((g,c); x_{in} \leftrightarrow x_{out}) = R_{eff}^{-1} = \pi(x_{in}) \cdot \mathbb{P}_{x_{in}}(\tau_{out} < \tau_{in}^+).$$
Exercise 1.4. It is not clear from Definition 1.5 that the effective conductance is a symmetric expression in $x_{in}$ and $x_{out}$ (i.e. there role can be interchanged). This is intuitively obvious if our interpretations are correct, but prove it only using the reversibility of the random walk.

We can give a quick interpretation of the effective resistance in terms of so-called the Green function of the random walk: For any $x \in V$ let $\tilde{G}(x)$ be the expected number of visits to $x$ by the random walk strictly before $\tau_{out}$. In particular $\tilde{G}(x_{out}) = 0$ and since the number of visits to $x_{in}$ is a geometric random variable with success parameter $P_{x_{in}}(\tau_{in} < \tau_{out})$ we have

$$\tilde{G}(x_{in}) = \frac{1}{1 - P_{x_{in}}(\tau_{in} < \tau_{out})} = \frac{1}{P_{x_{in}}(\tau_{in} > \tau_{out})} = \pi(x_{in})R_{eff}. $$

Hence the effective resistance is, up to the weight of $\pi(x_{in})$ the mean number of visits of $x_{in}$ before $\tau_{out}$. This interpretation still holds for any $v \in V$ if we add the potential in the game.

Definition 1.6. The Green function in $(g, c)$ started at $x_{in}$ and killed at $x_{out}$ is the function

$$G(x) = \frac{\tilde{G}(x)}{\pi(x)}. $$

Lemma 1.4. For all $x \in V$ we have $G(x) = R_{eff} \cdot v(x)$ where $v$ is the potential normalized so that $v(x_{in}) = 1$ and $v(x_{out}) = 0$.

Proof. Since we know the boundary conditions for $G(\cdot)$ the lemma follows from the uniqueness in the Dirichlet problem (Theorem 1.1) as soon as we have proved that the function $G$ is harmonic on $V \setminus \{x_{in}, x_{out}\}$. To prove this observe that if $x \notin \{x_{in}, x_{out}\}$ we have

$$G(x) = \frac{1}{\pi(x)} \mathbb{E}_{x_{in}}\left[ \sum_{k=1}^{\infty} 1_{X_k = x} 1_{\tau_{out} > k} \right] = \frac{1}{\pi(x)} \sum_{y \sim x} \mathbb{E}_{x_{in}}\left[ \sum_{k=1}^{\infty} 1_{X_{k-1} = y} 1_{X_k = x} 1_{\tau_{out} > k} \right]
$$

= \text{Markov} \ \ \frac{1}{\pi(x)} \sum_{y \sim x} \tilde{G}(y) p(y, x)

= \text{reversibility} \ \ \frac{1}{\pi(x)} \sum_{y \sim x} \tilde{G}(y) p(x, y) \frac{\pi(x)}{\pi(y)} \Rightarrow \text{harmonicity of } G. \ \ \ \Box

The last lemma enables us to give a wonderful interpretation of the resistance:

**Theorem 1.5 (Commute time captures the resistance [6])**

We have the following identity

$$R_{eff} \cdot \sum_{\vec{e} \in E} c(\vec{e}) = \mathbb{E}_{x_{in}}[\tau_{out}] + \mathbb{E}_{x_{out}}[\tau_{in}] \quad \text{commute time between } x_{in} \text{ and } x_{out}. $$
Proof. With the notation of the preceding proof we have
\[ E_{x_{\text{in}}} [\tau_{\text{out}}] = \sum_{x \in V} \tilde{G}(x) = R_{\text{eff}} \sum_{x \in V} \pi(x) \cdot v(x), \]
where \( v \) is the potential equal to 1 at \( x_{\text{in}} \) and 0 at \( x_{\text{out}} \). Reversing the roles of \( x_{\text{in}} \) and \( x_{\text{out}} \) ends up in changing \( v(\cdot) \) into \( 1 - v(\cdot) \). Summing the corresponding equalities, we get
\[ E_{x_{\text{in}}} [\tau_{\text{out}}] + E_{x_{\text{out}}} [\tau_{\text{in}}] = R_{\text{eff}} \sum_{x \in V} \pi(x). \]

Remark 1.4. This commute time identity reflects the fact that the effective resistance is in fact symmetric in exchanging the roles of \( x_{\text{in}} \) and \( x_{\text{out}} \) (see Exercise 1.4). It gives a practical and a theoretical tool to interpret resistance.

Exercise 1.5. For \( n \geq 2 \), let \( K_n \) be the complete graph on vertices \( \{0, 1, \ldots, n-1\} \), i.e. with an edge between each pair of vertices \( 0 \leq i \neq j \leq n-1 \). All the conductances are set to 1.

1. Compute \( R_{\text{eff}}((K_n, c \equiv 1); 0 \leftrightarrow 1) \).

2. Using the commute-time identify, deduce the expected hitting time of 1 for the random walk on \( K_n \) started from 0.

We now move on to a probabilistic interpretation of the current. Recall that the edge-random walk starting from \( x_{\text{in}} \) is a sequence of oriented edges \( (\vec{E}_n; n \geq 1) \). We denote \( S(\vec{e}) \) the number of times the random walk has gone through \( \vec{e} \) in that particular direction until we first reach the vertex \( x_{\text{out}} \). Then we have :

Proposition 1.6 (Probabilistic interpretation of the current). For any \( \vec{e} \in \vec{E} \) we have
\[ E_{x_{\text{in}}} [S(\vec{e}) - S'(\vec{e})] \cdot i_{\text{total}} = i(\vec{e}). \]

Proof. Observe that for a given oriented edge \( \vec{e} \) we have
\[ E[S(\vec{e})] = \sum_{k=0}^{\infty} \mathbb{P}_{x_{\text{in}}} (X_k = \vec{e}^* \text{ for } k < \tau_{\text{out}} \text{ and } \vec{E}_k = \vec{e}) \]
\[ = \tilde{G}(\vec{e}^*) \frac{c(\vec{e})}{\pi(x)} \text{ Lemma 1.4 } c(\vec{e}) \cdot R_{\text{eff}} \cdot v(\vec{e}^*). \]
Hence we have \( E_{x_{\text{in}}} [S(\vec{e}) - S'(\vec{e})] \cdot i_{\text{total}} = c(e) \cdot (v(\vec{e}^*) - v(\vec{e}^*')) = i(\vec{e}) \) by definition. \( \square \)

Exercise 1.6. Let \( ((g, c); x_{\text{in}}, x_{\text{out}}) \) be a network. Let \( T \) be a random spanning tree of \( g \) chosen with a probability proportional to
\[ \mathbb{P}(T = t) \propto \prod_{e \in T} c(e). \]
We write \( \{\vec{e} \in T\} \) for the event where the unique path from \( x_{\text{in}} \) to \( x_{\text{out}} \) in \( T \) traverses the edge \( \vec{e} \) in that particular direction. Prove that
\[ i(\vec{e}) = (\mathbb{P}(\vec{e} \in T) - \mathbb{P}(\vec{e}^* \in T)) \cdot i_{\text{total}}, \]
is the electric current. Hint: to show that the cycle rule is satisfied consider a random forest i.e. a pair \((T_{in}, T_{out})\) of trees attached to \(x_{in}\) and \(x_{out}\) whose weight is proportional to the product of the conductances of the edges. Show that \(P((a, b) \in T)\) is proportional to

\[
P(a \in T_{in}, b \in T_{out} \text{ and } T_{in} \cup T_{out} \cup \{a, b\} \text{ is a spanning tree}).
\]

Reminder on excursion theory. If \((g, c)\) is a weighted graph, the trajectory of a random walk starting from \(x\) can be decomposed in a succession of excursions away from \(x\). More precisely, if \(0 = \tau_x(0) < \tau_x^+ = \tau_x(1) < \tau_x(2) < \tau_x(3) \cdots\) are the successive return times of the walk to the point \(x\) then the excursions

\[
E^{(i)} = \left( X_{\tau_x^{(i)} + k} \right)_{0 \leq k < \tau_x^{(i+1)} - \tau_x^{(i)}},
\]

are independent identically distributed excursions (piece of a trajectory) starting and ending at \(x\). This is valid more generally as soon as the random walk is recurrent and is key to prove that the invariant measure (unique up to multiplicative constant) is given by

\[
\mu(y) = \mathbb{E}_x \left[ \sum_{k=1}^{\tau_x^+} 1_{X_k = y} \right]. \tag{1.1}
\]

In particular when the invariant measure is finite we deduce that

\[
\frac{\pi(x)}{\pi(V)} = \frac{1}{\mathbb{E}_x[\tau_x^+]}. \tag{1.2}
\]

The last formula and the excursion decomposition are used in the following exercises:

Exercise 1.7 (From [20]). Let \(G\) be a finite connected graph with \(n\) edges having all conductances equal to 1 and \((W_k)_{k \geq 0}\) be the associated random walk which starts from \(x \in V(G)\) under \(P_x\). We write \(\tau_x^+ = \inf\{k \geq 1 : W_k = x\}\) for the first return time to \(x\). Since the invariant measure on vertices for the random walk is proportional to the degree, we have by (1.2)

\[
\mathbb{E}_x[\tau_x^+] = \frac{2n}{\deg_G(x)}. \tag{1.3}
\]

The goal of the exercise is to give an “electrical” proof of this well-known fact. To do this, we consider the graph \(\tilde{G}\) obtained from \(G\) by adding a new vertex \(\tilde{x}\) attached to \(x\) via a single edge of conductance 1. We denote by \(\tau_{\tilde{x}}\) the hitting time of \(\tilde{x}\) by the random walk on \(\tilde{G}\). For clarity we denote by \(E\) the expectation under which the random walk moves on \(G\) and by \(E\) the expectation under which it moves along \(\tilde{G}\).

1. Show carefully that

\[
E_x[\tau_{\tilde{x}}] = \frac{1}{\deg_G(x) + 1} \sum_{k=0}^{\infty} \left( \frac{\deg_G(x)}{\deg_G(x) + 1} \right)^k (k \cdot E_x[\tau_x^+] + 1).
\]

2. Conclude using the commute time identity.
Exercise 1.8. Let \((g,c); x_{in}, x_{out}\) be a network. Consider \(\tau_{in}^+\) the first return time at \(x_{in}\) and \(\sigma_{in,out}\) the first return time to \(x_{in}\) after visiting \(x_{out}\), that is \(E_{x_{in}}[\sigma_{in,out}]\) is the commute time between \(x_{in}\) and \(x_{out}\). Show that \(\tau_{in}^+ \leq \sigma_{in,out}\) and that

\[
E_{x_{in}}[\sigma_{in,out} - \tau_{in}^+] = P_{x_{in}}(\tau_{in}^+ < \tau_{out})E_{x_{in}}[\sigma_{in,out}].
\]

Re-deduce Theorem 1.5.

Exercise 1.9. Let \((g,c)\) be a weighted graph with three distinguished points \(x,a,b \in V(g)\). By decomposing the random walk into independent and identically distributed excursions from \(x\) show that \(P_x(\tau_a < \tau_b) = P_x(\tau_a < \tau_b \mid \tau_{\{a,b\}} < \tau^+_x)\) and deduce

\[
P_x(\tau_a < \tau_b) \leq \frac{C_{eff}(x \leftrightarrow a)}{C_{eff}(x \leftrightarrow \{a,b\})}.
\]

Exercise 1.10. Let \((g,c)\) be a finite network with \(n\) vertices. Using (1.2) show that

\[
\sum_{e \in E(g)} i^e(e) = n - 1
\]

where \(i^e\) denotes the unit current flow from the origin to the extremity of \(e\).

1.2.3 Equivalent networks

Proposition 1.7. In a network we can perform the following operations without affecting the effective resistance (and in fact without changing the potential and the current outside of the current zone of transformation):

\[
c = (c_1^{-1} + c_2^{-1})^{-1}
\]

\[
c = c_1 + c_2
\]

\[
c_1 c_3 = \frac{c_1 c_2 c_3}{c_1 + c_2 + c_3}
\]

Figure 1.3: The series and parallel transformations. The last one is known as the star-triangle transformation.
Proof. For the series rule, the current flowing through the two edges must be the same hence the resistances add up. For the parallel rule, the potential difference between the two edges are the same hence the conductances add up. For the star-triangle transformation, one has to check that whatever the potentials \((v_1, v_2, v_3)\) the current flowing from the three apexes are the same in the two circuits. If \(\alpha\) denotes the value of the potential in the middle of the “star” replacing the triangle we must have

\[
(c_1 + c_2 + c_3)\alpha = c_1 v_1 + c_2 v_2 + c_3 v_3
\]

and

\[
(v_1 - \alpha)c_1 = (v_1 - v_2)c_3 + (v_1 - v_3)c_2,
\]

\[
(v_2 - \alpha)c_1 = (v_2 - v_1)c_3 + (v_2 - v_3)c_1,\]

\[
(v_3 - \alpha)c_1 = (v_3 - v_1)c_2 + (v_3 - v_2)c_1.
\]

Since these equality must be true for all \(v_1, v_2, v_3\) this indeed imposes \(c_ic_i = c_1c_2c_3/(c_1+c_2+c_3)\)

(we leave as an exercise to see that this defines uniquely the \(c_i\)'s).

\(\square\)

Exercise 1.11 (From [19]). Find \(\mathbb{P}(\tau_{\text{out}} < \tau_{\text{in}}^+)\) in the two networks where all conductances are equal to 1:

Exercise 1.12. Compute the effective resistance in the following sequence of networks (the Sierpinski triangles):

1.3 Energy and variational principles

We finally explore the mathematical interpretation of the “Joule heating”. Rather that a probabilistic interpretation, this will motivate the introduction of a functional, the energy – physically this is rather a power–, which the electrical potential minimizes. This is a general concept in physics: we can usually describe the behavior of some process by local laws (here Ohm’s law, flow and cycle rules etc) or by the minimization of some potential “the least action principle”. The outcome in maths are variational principles for the potential/current which are
softer to use and in particular enables us to prove inequalities instead of computing exactly the quantities of interests.

1.3.1 Energy

Definition 1.7. Let $(g, c); x_{in}, x_{out}$ be a finite network, $j : x_{in} \rightarrow x_{out}$ be a flow in the graph and $f : V(g) \rightarrow \mathbb{R}$ be a function on its vertices. The energy of the flow $j$ and of the function $f$ are by definition (with a slight abuse of notation)

$$E(j) := \frac{1}{2} \sum_{\vec{e} \in \vec{E}} j(\vec{e})^2 / c(\vec{e})$$

$$E(f) := \frac{1}{2} \sum_{\vec{e} \in \vec{E}} c(\vec{e}) \cdot (\nabla \vec{e} f)^2.$$

Notice that the factors 1/2 are present in the definition to count each non-oriented edge once in the definition (this is only a matter of convention). In the case of the electric current $i$ and the associated electric potential $v$, the two energies agree and are

$$E(i) = E(v) = \sum_{e \in E} i(e)^2 / c(e)$$

$$= \frac{1}{2} \sum_{\vec{e} \in \vec{E}} c(\vec{e})(\nabla \vec{e} v)^2$$

$$= \sum_{x \in V} v(x) \sum_{\vec{e} = (x,y)} c(\vec{e})(v(x) - v(y))$$

$$= \sum_{v(x_{in})=0}^{v(x_{out})=0} \sum_{\vec{e} = (x_{in}, \cdot)} c(\vec{e})(v(x_{in}) - v(\vec{e}^*))$$

$$= \Delta v \cdot i_{total} = R_{eff} \cdot (i_{total})^2 = C_{eff} \cdot (\Delta v)^2. \quad (1.4)$$

1.3.2 Variational principles

We now give two variational principles for the energy:

Theorem 1.8 (Thomson’s principle)

If $j : x_{in} \rightarrow x_{out}$ is a flow of the same total flux as $i$ then $E(i) < E(j)$ with equality if and only if $i = j$. In words, the electric current minimizes the energy for a given flux and

$$R_{eff}((g, c); x_{in} \leftrightarrow x_{out}) = \min\{E(j) : j : x_{in} \rightarrow x_{out} \text{ unit flow}\}.$$

Proof. By assumptions $j$ satisfies the flow rule and has the same flux as $i$. We consider the flow $i - j$ which has then 0 flux. It is easy to see that we can decompose any 0-flux flow into a sum of currents along oriented cycles. However, it is easy to see that any current along a cycle is orthogonal (for the scalar product whose normed squared is the energy) with respect to $i$. 19
Hence we get that
\[ E(j) = E(i + (j - i)) = E(i) + \sum_{\text{cycles}} (i | j - i) = E(i), \]
and with equality if and only if \( i = j \) as Thomson\(^8\) wanted. The display in the theorem then follows from (1.4).

**Theorem 1.9 (Dirichlet’s principle)**

If \( f : V(g) \to \mathbb{R} \) such that \( f(x_{in}) = v(x_{in}) \) and \( f(x_{out}) = v(x_{out}) \) is a function with the same boundary conditions as the electrical potential then \( \mathcal{E}(v) < \mathcal{E}(f) \) with equality if and only if \( v = f \). In words, the electric potential minimizes the energy for a given boundary condition

\[
C_{\text{eff}}((g, c); x_{in} \leftrightarrow x_{out}) = \min \{ \mathcal{E}(f) : f : V(g) \to \mathbb{R} \text{ such that } f(x_{in}) = 1 \text{ and } f(x_{out}) = 0 \}.
\]

**Proof.** The proof is almost the same as for Thomson’s principle and reduces to showing that for the scalar product whose norm is \( \mathcal{E}(,.) \) the set of 0-boundary condition functions \( f \) is orthogonal to the set of functions which are harmonic except at the boundary. We leave the details as an exercise for the reader.

The great advantage of the last two results is that if we want upper and lower bounds on the resistance, we just need to produce a flow or a function rather that computing exactly the value of the resistance. This flexibility will be used a lot in the next chapter. Here is some “trivial” corollary whose physical interpretation is clear, but whose proof is far from obvious without the tools developed in this chapter!:

**Corollary 1.10 (Rayleigh monotonicity).** The effective conductance is a non-decreasing function of each conductance of the graph.

**Proof.** Let \( c \leq c' \) two conductances on the same graph \( g \). We write \( i \) and \( i' \) respectively for the electrical current carrying a unit flux (in particular, the two potential differences may be different). We write \( \mathcal{E}_c \) for the energy relative to the conductances \( c \). Then we have

\[
R_{\text{eff}}((g, c); x_{in} \leftrightarrow x_{out}) = \mathcal{E}_c(i) \geq \mathcal{E}_{c'}(i) \geq \mathcal{E}_{c'}(i') = R_{\text{eff}}((g, c'); x_{in} \leftrightarrow x_{out}).
\]

**Remark 1.5.** The result of Rayleigh\(^9\) is very useful: we can modify the graph in order to estimate the effective resistance. In particular, if the conductance of an edge is put to 0 this boils down to just removing the edge from the graph whereas if its conductance is set to \( \infty \) it is equivalent to identifying its extremities.

---

\(^8\) Joseph John Thomson (1856-1940)

\(^9\) John William Strutt, 3rd Baron Rayleigh (1842–1919)
Exercise 1.13. Suppose that the resistances of the finite graph \( g \) denoted by \((r(e), e \in \text{E}(g))\) are variables. The effective resistance \( R_{\text{eff}}(r) = R_{\text{eff}}((g, r^{-1}); x_{\text{in}}, x_{\text{out}}) \) is thus a function of \((r(e) : e \in \text{E}(g))\).

1. Show that the derivative of \( R_{\text{eff}} \) with respect to \( r(e) \) is given by \( i(e)^2 \) where \( i \) is the unit-flow electrical current going through \( e \).

2. Deduce that \( R_{\text{eff}} \) is a concave function of each resistance.

Exercise 1.14 (From Arvind Singh). (*) Let \((g, c; x_{\text{in}}, x_{\text{out}})\) be a finite network and let \( i = x_{\text{in}} \to x_{\text{out}} \) the unit-flux electrical current flowing from \( x_{\text{in}} \) to \( x_{\text{out}} \). Show that for every edge \( e \in \text{E}(g) \) we have \(|i(e)| \leq 1\).

1.4 Discrete Gaussian Free Field

In this section we introduce the discrete Gaussian free field. Although not used in the rest of these lecture notes, this random object is central in probability theory and especially in planar random geometry. We will see that its definition is intimately connected with the electric notions that we developed so far and this gives us an excuse to shed new light on a few calculations we performed in the preceding pages. In the remaining of this section \((g, c)\) is a finite weighted graph and \( \partial g \) is a set of (at least one) distinguished vertices of \( g \) (previously we had \( \partial g = \{x_{\text{in}}, x_{\text{out}}\} \)).

1.4.1 The “physics” definition

Given \(((g, c); \partial g)\), the discrete Gaussian Free Field (GFF) with zero boundary condition on \( \partial g \) is a random function \( H : V(g) \to \mathbb{R} \) which vanishes on \( \partial g \). It models the fluctuations of a membrane or a system of springs. As usual in physics, the probability distribution is related to the potential energy of the system through the formalism of Gibbs measure, in our case this boils down to considering the following density

\[
\frac{1}{C} \exp \left( -\frac{1}{2} \cdot \frac{1}{2} \sum_{\vec{e} \in \text{E}(g)} c(\vec{e})(\nabla_{\vec{e}} H)^2 \right),
\]

with respect to the product Lebesgue measure on \( \mathbb{R}^{V(g) \setminus \partial g} \) where the coordinates along vertices on the boundary are set to 0. The first 1/2 in the exponential is here to count each non-oriented edge only once, the second one is the usual factor in the density of the standard Gaussian distribution. The normalization constant \( C > 0 \) is, at this stage, inexplicit (see Exercise 1.15). This definition immediately raises the question of the individual law of \( H(x) \) and the correlations between values at different points. To answer these questions, we first need some background and an equivalent definition of \( H \).
1.4.2 The $\ell^2$-definition

Another definition of the discrete GFF goes through the $L^2$ machinery of Gaussian processes. Consider the space $\ell^2_0$ of functions $f : V(g) \to \mathbb{R}$ that are vanishing on $\partial g$. It is easy to see that this space can be turned into a Hilbert space of dimension $\#V(g) - \#\partial g$ endowed with the inner product

$$<f, g> = \frac{1}{2} \sum_{(x,y) \in E(g)} c(e) \nabla_e f \cdot \nabla_e g,$$

where the factor $1/2$ is here to count each non-oriented edge once in the definition. Its associated norm is nothing but $E(f)$, the energy of $f$ seen in the last section. Now, as soon as we are in possession of a finite dimensional Hilbert space, one can canonically construct a Gaussian random variable on it:

**Definition 1.8.** If $(E, <\cdot, \cdot>)$ is a finite dimensional Hilbert space with an orthonormal basis $(e_1, \ldots, e_n)$. Then the following random variable is well-defined and its law does not depend on the choice of the orthonormal basis:

$$H = \sum_{i=1}^{n} N_i \cdot e_i \in E,$$

where $N_i$ are independent identically distributed standard real Gaussian variables. The law of $H$ is called the “Gaussian distribution” on $(E, <\cdot, \cdot>)$.

To see that the law of $H$ does not depend on the orthonormal basis, we just have to remark that if $Z_i$ are the coefficients of $H$ in another orthonormal basis $(f_1, \ldots, f_n)$ then these are obtained from $N_1, \ldots, N_n$ by multiplication by an orthogonal matrix. But by standard properties of Gaussian vectors we then have $(Z_i)_{1 \leq i \leq n} = (N_i)_{1 \leq i \leq n}$.

**Exercise 1.15.** Show that in our case the law of $H$ agrees with (1.5) and prove in particular that the constant $C > 0$ is explicitly given by

$$C = \sqrt{2 \pi}^n \det(e_i(x_j))_{1 \leq i, j \leq n},$$

where $x_1, \ldots, x_n$ are the $n$ vertices of $g \setminus \partial g$ and $e_1, \ldots, e_n$ is an orthonormal basis of $\ell^2_0$.

1.4.3 Expression of the covariance

By Definition 1.8, the random function $H$ is Gaussian, that is, any linear combination of its entries is Gaussian (and centered). It is then natural to explicit the distribution of $H$ which is encoded in its covariance structure. The starting point is to notice the following integration by
part formula (that we already used implicitly in Equation 1.4 of Chapter 1):

\[ <f, g> = \frac{1}{2} \sum_{(x,y) \in \mathcal{E}(g)} (f(x) - f(y))(g(x) - g(y))c((x, y)) \]

\[ = \sum_{x \in \mathcal{V}(g) \setminus \partial g} f(x) \sum_{y \sim x} (g(x) - g(y))c(x, y) \]

\[ = - \sum_{x \in \mathcal{V}(g) \setminus \partial g} f(x) \pi(x) \Delta g(x), \]

where we introduced the discrete Laplacian operator \( \Delta \) acting on functions \( g : \mathcal{V}(g) \to \mathbb{R} \):

\[ \Delta g(x) = \sum_{y \sim x} p(x, y)(g(y) - g(x)) = \mathbb{E}_x[g(X_1) - g(x)]. \]

Hence, if \( g_x(\cdot) \) is a function such that \( \Delta g_x(\cdot) \) is zero inside \( \mathcal{V}(g) \setminus \partial g \) except at \( x \) where it is equal to \( \frac{-1}{\pi(y)} \) then we have \( <f, g_x> = f(x) \). It is easy to see that such a function exist, more generally one can always find a function \( f \) satisfying

\[ (*) \quad \begin{cases} f = f_0 & \text{on } \partial g, \\ \Delta f = u_0 & \text{on } \mathcal{V}(g) \setminus \partial g, \end{cases} \]

where \( u_0 \) and \( f_0 \) are two prescribed functions. Indeed, using our knowledge on the Dirichlet problem, we easily deduce that the above problem has at most one solution (since the difference of two solutions solves the Dirichlet problem with zero boundary condition). The existence can also be deduced using similar lines as those developed in Chapter 1 and the reader can check that a solution can be represented probabilistically as follows (exercise!)

\[ f(x) = \mathbb{E}_x \left[ f_0(X_{\tau_{\partial g}}) - \sum_{k=0}^{\tau_{\partial g} - 1} u_0(X_k) \right]. \]

When \( f_0 = 0 \) and \( u_0(\cdot) = \delta_x \), we recover the fact that the function \( \mathbb{E}_x[\# \text{ visits to } y \text{ before } \tau_{\partial g}] \) is harmonic in \( y \) except at \( y = x \) (this was already observed in Lemma 1.4) and if we recall the definition of the Green function (Definition 1.6) where the dependence in the starting point is now stressed:

\[ G(x, y) = \frac{1}{\pi(y)} \mathbb{E}_x[\# \text{ visits to } y \text{ before } \tau_{\partial g}], \]

then we have \( G(x, y) = G(y, x) \) and \( G \) is harmonic in both coordinates except on the diagonal where its Laplacian equal \( \frac{-1}{\pi(y)} \). We can thus come back to our quest and prove

**Proposition 1.11.** The covariance structure of the discrete Gaussian free field is given by

\[ \text{Cov}(H(x), H(y)) = G(x, y). \]

In particular we have \( \mathbb{E}[H(x)^2] = R_{\text{eff}}((g, c); x \leftrightarrow \partial g). \)
Proof: Fix $x, y \in V(g) \setminus \partial g$. By the above reasoning we deduce that $G(x, \cdot)$ and $G(y, \cdot)$ are two functions of $\ell^2_0$ which are harmonic in $V(g) \setminus \partial g$ except respectively at $x$ and $y$ where they satisfy $\Delta G(x, \cdot)|_x = -\frac{1}{\pi(x)}$ and $\Delta G(y, \cdot)|_y = -\frac{1}{\pi(y)}$. By the above remark we have

$$H(x) = -\sum_z H(z)\pi(z)\Delta g_x(z) = <H, gx>,\quad H(y) = -\sum_z H(z)\pi(z)\Delta g_y(z) = <H, gy>,$$

so that

$$\text{Cov}(H(x), H(y)) = \mathbb{E}[H(x)H(y)]$$

$$= \mathbb{E}\left[\left\langle \sum_{i=1}^n \mathcal{N}_i e_i | G(x, \cdot) \right\rangle \left\langle \sum_{i=1}^n \mathcal{N}_i e_i | G(y, \cdot) \right\rangle\right]$$

$$= <G(x, \cdot)|G(y, \cdot)>$$

$$= -\sum_z G(x, z)\pi(z)\Delta G(y, \cdot)|_z$$

$$= G(x, y).$$

When $x = y$ we have $G(x, x) = R_{\text{eff}}((g, c); x \leftrightarrow \partial g)$ as proved in Lemma 1.4. \hfill \Box

1.4.4 The statistics definition

The action (1.5) defining the discrete GFF but also pops up in statistics. Assume that on each vertex of your graph $g$ this is a mountain, a peak, whose altitude you want to measure. Alas, you only know that the peaks on $\partial g$ are at height 0 and you are only able to measure altitude differences along edges of your graph (once for each edge)... but with an independent Gaussian error with variance $1/c(e)$. Performing all these measurements you end-up with a collection of noisy height differences

$$\hat{\nabla}(\vec{e}) = \mathcal{N}_e + \nabla_e h_0,$$

where the function $h_0$ is the true height and the errors are independent for each non-oriented edges and so that $\mathcal{N}_e = -\mathcal{N}_{\vec{e}}$. What is then the best estimator of the true height of the peaks? The maximum likelihood estimator returns the function $h$ minimizing the Gaussian errors i.e.

$$\arg\min_h \exp\left(\frac{1}{4} \sum_{\vec{e} \in \hat{E}(g)} c(e) \left(\hat{\nabla}(\vec{e}) - \nabla_e h\right)^2\right),$$

so that if $h = h_0 + H$ the (random) function $H$ minimizes

$$\sum_{\vec{e} \in \hat{E}(g)} c(\vec{e}) \left(\nabla_e H - \mathcal{N}_{\vec{e}}\right)^2.$$  \hfill (1.6)
Proposition 1.12. The function $H$ minimizing (1.6) is distributed as the discrete Gaussian Free Field on $((g, c); \partial g)$.

Proof. The Hilbert space $\ell^2_0$ can be embedded in the larger Hilbert space $\ell^2_{\text{sym}}$ of antisymmetric functions $\theta = \vec{E} \to \mathbb{R}$ on oriented edges. Indeed on $\ell^2_{\text{sym}}$ we can define the inner product

$$< \theta, \psi > = \frac{1}{2} \sum_{\vec{e}} c(\vec{e}) \theta(\vec{e}) \cdot \psi(\vec{e}),$$

and we embed $f \in \ell^2_0 \mapsto (\nabla_{\vec{e}} f)_{\vec{e}} \in \ell^2_{\text{sym}}$ so that the inner products match. In particular, the minimization problem (1.6) is nothing but the projection onto the smaller $\ell^2_0$ space made of those functions on oriented edges that actually come from “derivatives” of usual functions on vertices. But the function $N = (N_{\vec{e}})_{\vec{e}} \in \ell^2_{\text{sym}}$ is standard Gaussian in $\ell^2(\vec{E})$ and thus its coordinates are i.i.d. standard Gaussian in any orthonormal basis. We just have to form such a basis by starting with the basis for $\ell^2_0$ used in Definition 1.8 and then complete with a basis of the orthogonal. After the projection, we end-up with a function of $\ell^2_0$ (hence the derivative of a function) whose coefficients in the basis of Definition 1.8 are just i.i.d. standard normals as wanted.

Remark 1.6. The discrete Gaussian Free Field is also related to random walks on $(g, c)$ via “Dynkin type” isomorphisms relating the occupation (local) times of a random walk to version of the discrete Gaussian free field, see [18]. More generally, the (discrete and continuous) Gaussian free field pops up in many context such as Liouville conformal field theory in dimension 2, uniform spanning trees, loop erased random walks etc. The interested reader should consult the bible [19] and the references therein for much more on this wonderful object.
Chapter II: Infinite graphs and recurrence/transience

In this chapter we use the connection between potential theory, electrical networks and random walks to give robust and practical recurrence/transience criteria for infinite graphs. Here \((g,c)\) is a weighted infinite connected graph whose degrees are all finite. In particular the vertex set \(V\) is countable and the random walk on \((g,c)\) is irreducible.

2.1 Recurrence and resistance

If \(x_{in} \in V\) we recall that under \(P_{x_{in}}\) the process \((X_n)_{n \geq 0}\) is the random walk (directed by the conductances \(c\)) on the graph \(g\) and started from \(X_0 = x_{in}\). The classical dichotomy for irreducible countable Markov chains then ensures that either \(X_n = X_0\) for infinitely many \(n\)'s in which case \((g,c)\) is called recurrent, otherwise \(X_n = X_0\) finitely many times (and even \(E[\sum_n 1\{X_n = X_0\}] < \infty\) and the graph is transient\(^1\)). To relate these concepts with the effective resistance we consider

\[ x_{in} = g_0 \subset g_1 \subset \cdots \subset g_n \subset \cdots \subset g, \]

an exhaustion of \(g\) i.e. an increasing sequence of finite connected subgraphs of \(g\) such that \(\cup g_n = g\). We denote by \(\partial g_n\) the set of vertices of \(g_n\) which have a neighbor in \(g\) which is not in \(g_n\). We can interpret \(g_n\) as a finite network where the conductances are inherited from \(g\) and where \(x_{out} = \partial g_n\) where all the vertices are collapsed into a single vertex. By the result of the last chapter we have

\[
\pi(x_{in}) P_{x_{in}}(\tau_{out} < \tau_{in}^+) = C_{\text{eff}}\left((g_n,c); x_{in} \leftrightarrow \partial g_n\right) \xrightarrow{n \to \infty} \pi(x_{in}) P_{\rho}(\tau_{in}^+ = \infty) := C_{\text{eff}}\left((g,c); x_{in} \leftrightarrow \infty\right). 
\]

Using Rayleigh’s monotonicity it is easy to see that the above definition does not depend on the exhaustion of the graph: if \((g'_n)_{n \geq 0}\) is another exhaustion then for any \(n \geq 0\) we can find \(m,p \geq 0\) such that \(g_n \subset g'_m \subset g_p\) and by monotonicity of the conductance

\[
C_{\text{eff}}\left((g_n,c); x_{in} \leftrightarrow \partial g_n\right) \geq C_{\text{eff}}\left((g'_m,c); x_{in} \leftrightarrow \partial g'_m\right) \geq C_{\text{eff}}\left((g_p,c); x_{in} \leftrightarrow \partial g_p\right),
\]

hence the limits are the same. We have thus proved:

**Proposition 2.1.** The graph \((g,c)\) is recurrent if and only if there exists (equivalently: for all) \(x_{in} \in V\) such that the effective conductance between \(x_{in}\) and \(\infty\) is equal to 0 (the effective resistance is infinite).

\(^1\)and the notion does not depend upon \(x_{in} \in V\)
Example 2.1. The line $\mathbb{Z}$ is recurrent when all conductances are equal to 1 (all trees with at most two ends are recurrent). By monotonicity of the resistance, if $(g, c)$ is recurrent then so is any subgraph of it (with the same conductances): this is not trivial even in the case of subgraphs of $\mathbb{Z}^2$.

Exercise 2.1. Show that the complete binary tree is transient.

2.2 Criterions for recurrence/transience

We establish a few useful criteria to determine recurrence/transience.

2.2.1 Nash-Williams cutsets

Instead of giving the Nash-Williams criterion in its full generality (see Proposition 2.3) we illustrate the most common application which readily follows from monotonicity of the effective resistance. Fix $(g, c)$ a weighted infinite graph and $x_{in} \in V$. A cutset between $x_{in}$ and $\infty$ in the graph $g$ is a subset $\Gamma$ of edges such that any path $\gamma : x_{in} \to \infty$ must pass through $\Gamma$. Imagine that we can build in the graph $(g, c)$ a sequence of disjoints cutsets $\Gamma_1, \Gamma_2, \ldots$ which are nested in the sense that we can contract all the edges of the graph except those on the cutsets and identify vertices to obtain a line graph with parallel edges belonging to $\Gamma_1, \Gamma_2, \ldots$, see below.

\[ R_{\text{eff}}((g, c); x_{in} \leftrightarrow \infty) \geq R_{\text{eff}}\left(\sum_{i=1}^{\infty} \left(\sum_{e \in \Gamma_i} c(e)\right)^{-1}\right). \]

27

\[ \text{Crispin St. John Alvah Nash-Williams 1932–2001} \]
Application to $\mathbb{Z}^2$. The last method can be successfully applied in the case of $\mathbb{Z}^2$ (with the obvious edge set and with all conductances equal to 1): the disjoints cutsets made of the edges in-between $[-n,n]^2$ and $[-(n+1),n+1]^2$ have size $4(2n+1)$ and so the effective resistance between 0 and $\infty$ in $\mathbb{Z}^2$ is larger than $\sum_{n=0}^{\infty} \frac{1}{4(2n+1)} = \infty$. This proves that $\mathbb{Z}^2$ (as well as any subgraph of it!) is recurrent.

**Exercise 2.2.** Consider the graph $\mathbb{Z}^3$ made of a stack of horizontal copies of $\mathbb{Z}^2$. We split each vertical edge at height $i \geq 1$ in-between two copies of $\mathbb{Z}^2$ into $|i|$ edges in series. Our goal is to prove that the resulting graph $G$ where all the conductances are equal to 1 is recurrent.

1. Prove that we cannot find disjoint cutsets for which we can apply Nash-Williams criterion and deduce recurrence.

We now split the edges in each horizontal $\mathbb{Z}^2$ as follows: for $n \geq 1$ each edge connecting $[-n,n]^2$ to $[-(n+1),(n+1)]^2$ is split in $n$ edges in series, each of which has conductance $1/n$. The new weighted graph is denoted by $G'$.

3. Prove that $G$ and $G'$ are equivalent.

4. Find good cutsets in $G'$ in order to apply Nash-Williams criterion and deduce recurrence.

### 2.2.2 Variational principles

We now use Theorem 1.8 to give a transience criterion in the infinite setting due to Terry Lyons\(^3\):

**Theorem 2.2 (T. Lyons)**

The graph $(g,c)$ is transient if and only if there exists (equivalently for all) $x_{in} \in V$ such that we can create a flow $j : \vec{E} \to \mathbb{R}$ of unit flux whose only source is $x_{in}$ and with finite energy i.e.

$$\mathcal{E}_c(j) = \sum_{e \in E} \frac{j(e)^2}{c(e)} < \infty.$$ 

**Proof.** In order to use the result on the finite setting we fix $(g_n)_{n \geq 0}$ an exhaustion of the graph $g$. Suppose first that we possess a flow as in the theorem. By restricting it to $g_n$ we obtain a unit flow $x_{in} \to \partial g_n$ whose energy is bounded by the energy of the total flow. Using Theorem 1.8 we deduce that the energy of the unit electric courant $i_n : x_{in} \to \partial g_n$ is also bounded by the same constant, and this proves

$$\forall n, \quad \text{R}_{\text{eff}}((g_n,c); x_{in} \leftrightarrow \partial g_n) \leq \mathcal{E}_c(j) < \infty.$$ 

By passing to the limit $n \to \infty$ we deduce that the effective resistance to $\infty$ is indeed finite and so the graph is transient.

Conversely, if $(g,c)$ is transient we know that the unit electric current flow $i_n : x_{in} \to \partial g_n$ has an

---

\(^3\)Terence "Terry" John Lyons (born 1953)
energy bounded above by the resistance between \( x_{\text{in}} \) and \( \infty \) in the graph. By taking a diagonal extraction if necessary we can consider a sub sequential limit unit flow \( i_{n \to \infty} \to j \). An application of Fatou’s lemma then entails that the energy of this flow is again bounded by the resistance between \( x_{\text{in}} \) and \( \infty \) in the graph.

Random path. Here is a convenient method to build a unit flux on a graph. Suppose that we dispose of a random infinite oriented path \( \vec{\Gamma} \) starting from \( x_{\text{in}} \). Erasing loops if necessary, we can suppose that \( \vec{\Gamma} \) is a simple path. We then put

\[
j(\vec{e}) = \mathbb{P}(\vec{\Gamma} \text{ goes through } \vec{e} \text{ in that direction}).
\]

Because \( \vec{\Gamma} \) is infinite and starts at \( x_{\text{in}} \) it is easy to check that \( j \) is indeed a unit flow whose only source is \( x_{\text{in}} \). Bounding the energy of \( j \) reduces to bounding \( \sum_{e \in E} \mathbb{P}(e \in \Gamma)^2 \).

Application to \( \mathbb{Z}^d \) with \( d \geq 3 \). Let \( \mathbb{Z}^d \) be the \( d \)-dimensional lattice with the usual edge set and conductances equal to 1. We imagine that \( \mathbb{Z}^d \) is embedded in \( \mathbb{R}^d \) is the natural way. We then consider \( \gamma \subset \mathbb{R}^d \) a random semi infinite line starting from 0 such that its intersection with the unit sphere is uniform on the \( d - 1 \) surface. We can then approximate in the discrete \( \gamma \) by a simple oriented path \( \vec{\Gamma} \) which stays within a constant distance from \( \gamma \). It is then easy to see that

\[
\sum_{e \in \mathbb{Z}^d} \mathbb{P}(e \in \Gamma)^2 \approx \sum_{e \in \mathbb{Z}^d} (\text{dist}(0, e))^{2(1-d)} \approx \sum_{r=1}^{\infty} \frac{1}{r^{d-1}} < \infty \text{ whenever } d \geq 3,
\]

and so by Theorem 2.2 the graphs \( \mathbb{Z}^d \) are transient when \( d \geq 3 \).

We can also use the flow criterion in order to prove a strong version of the Nash-Williams criterion without assuming any geometric condition on the cutsets:

**Proposition 2.3.** Suppose that \( \Gamma_1, \Gamma_2, \ldots \) are disjoint cutsets separating \( x_{\text{in}} \) from \( \infty \) in \( g \). We then have

\[
\sum_{i \geq 1} \left( \sum_{e \in \Gamma_i} c(e) \right)^{-1} = \infty \quad \Rightarrow \quad (g, c) \text{ is recurrent.}
\]

**Proof.** If \( (g, c) \) is transient then by Theorem 2.2 there exists a unit flow \( j \) with source \( x_{\text{in}} \) and finite energy. Clearly the unit flux has to escape through any cutset \( \Gamma_i \) which means that \( \sum_{e \in \Gamma_i} |j(e)| \geq 1 \). On the other hand by Cauchy–Schwarz we have

\[
1 \leq \left( \sum_{e \in \Gamma_i} |j(e)| \right)^2 \leq \left( \sum_{e \in \Gamma_i} j(e)^2/c(e) \right) \left( \sum_{e \in \Gamma_i} c(e) \right),
\]

hence \( (\sum_{e \in \Gamma_i} j(e)^2/c(e)) \geq (\sum_{e \in \Gamma_i} c(e))^{-1} \) and summing over \( i \geq 0 \) leads a contradiction to the finiteness of the energy. \( \square \)
Exercise 2.3 (From [19]). If $A \subset \mathbb{Z}^d$ for $d \geq 1$ we denote by $G_A$ the subgraph whose vertices are indexed by $A$ and whose edges are inherited from the standard edges in $\mathbb{Z}^d$. All the conductances are set to 1. Let $f : \mathbb{N} \to \mathbb{N}^*$ be a non-decreasing function. We write $A_f = \{(x, y, z) \in \mathbb{Z}^3 : x, y \geq 0, 0 \leq z \leq f(x)\}$.

1. Show that $\sum_{n \geq 1} \frac{1}{nf(n)} = \infty \implies G_{A_f}$ recurrent.

2. We suppose that $\forall n \geq 0, f(n+1) \leq f(n) + 1$. Show the converse to the last implication (Hint: Consider a random path in $G_{A_f}$ close to $(n, U_1 n, U_2 f(n))$ where $U_1, U_2$ are i.i.d. uniform over $[0, 1]$).

Exercise 2.4 (First passage percolation). Let $g$ be an infinite graph. We endow each edge of $g$ with an independent exponential edge weight $\omega_e$ of parameter 1 which we interpret as a length. The first-passage distance is then defined as

$$d_{fpp}(x, y) = \inf \left\{ \sum_{e \in \gamma} \omega_e : \gamma \text{ is a path } x \to y \right\}.$$ 

Show that if $\mathbb{E}[d_{fpp}(x_in, \infty)] < \infty$ then $g$ is transient (with unit conductances).

As Lyons’ criterion follows from a passage to the limit in Thomson criterion in the finite setting (Theorem 1.8), a recurrence criterion can easily be deduced from Dirichlet’s formulation of the resistance (Theorem 1.9). We leave the proof as an exercise for the reader.

**Theorem 2.4**

The graph $(g, c)$ is recurrent if and only if there exists (equivalently for all) $x_{in} \in V$ such that we can create a functions $f_n : V \to \mathbb{R}$ with $f_n(x_{in}) = 1$ and $f_n = 0$ outside of a finite set of vertices whose energy $\mathcal{E}_c(f_n)$ are tending to 0 as $n \to \infty$.

2.3 Perturbations

In this section we will prove that the concept of recurrence/transience is stable under perturbations of the underlying lattice as long as they are not too severe at large scales. We will restrict ourselves to the case of “bounded geometry” where vertex degrees and conductances are bounded away from 0 and $\infty$.

2.3.1 Quasi-isometries

**Definition 2.1.** Let $(E, d)$ and $(F, \delta)$ two metric spaces. A map $\phi : E \to F$ is a quasi-isometry if there exist $A, B > 0$ such that

(i) $\forall y \in F, \exists x \in E, \quad \delta(y, \phi(x)) \leq B$, “quasi-surjectivity”

(ii) $\forall x, x' \in E, \quad \frac{1}{A}d(x, x') - B \leq \delta(\phi(x), \phi(x')) \leq A d(x, x') + B$ “quasi-isometry”. 

30
If there exists a quasi-isometry between \((E, d)\) and \((F, \delta)\) then the two spaces are said to be quasi-isometric. Sometimes this notion is also called rough isometry or coarse isometry. It is an exercise to see that being quasi-isometric is an equivalence relation on all metric spaces.

**Example 2.2.** The trivial mapping \(\mathbb{Z}^d \to \mathbb{R}^d\) shows that they are quasi isometric. All finite metric spaces are trivially quasi isometric to a point. If two graphs \(g\) and \(g'\) (endowed with their graph metrics) are quasi isometric then the share the same rough rate of growth of balls. We deduce in particular that \(\mathbb{Z}^d\) is not quasi-isometric to \(\mathbb{Z}^d'\) if \(d \neq d'\).

**Exercise 2.5 (A few geometric comparisons).** (*) We write \(\simeq\) for the quasi-isometry relation. All graphs are endowed with the graph distance.

- Prove \(T_3 \simeq T_4\) where \(T_d\) is the infinite tree where all vertices have degree \(d \geq 1\).
- Show that \(\mathbb{Z}^2 \not\simeq \mathbb{Z} \times \mathbb{N} \simeq \mathbb{N}^2\).
- (Benjamini & Shamov [3]) Show that the bijective quasi-isometries of \(\mathbb{Z}\) are within bounded distance for the \(\|\cdot\|_\infty\) norm from either identity or -identity.

**Exercise 2.6 (Open question of G. Kozma (**).** Does there exist a bounded degree graph which is quasi-isometric to \((\mathbb{R}^2, \|\cdot\|_2)\) where the multiplicative constant \(A\) in the quasi-isometry Definition 2.1 is equal to 1?

2.3.2 Invariance with respect to quasi-isometries

**Theorem 2.5 (recurrence is quasi-isometry invariant)**

Let \(g\) and \(g'\) two quasi isometric infinite graphs. Suppose that the vertex degrees and the conductances of \(g\) and \(g'\) are bounded away from 0 and \(\infty\). Then \((g, c)\) is recurrent if and only if \((g', c')\) is recurrent.

**Proof.** Suppose that \((g, c)\) is transient and that \(\phi : g \to g'\) is a quasi-isometry. Up to replacing parallel edges and removing loops we can suppose that \(g\) is a simple graph. By our assumption and Theorem 2.2 there exists a unit flux flow \(j : \vec{E}(g) \to \mathbb{R}\) from \(x_{in} \to \infty\) whose energy is finite. We will transform this flow into a flow on \(\vec{E}(g')\). More precisely for each edge \(\vec{e} = (x, y) \in \vec{E}(g)\) we choose an oriented geodesic path in \(g'\) from \(\phi(x)\) to \(\phi(y)\). We denote this path \(\phi(\vec{e})\). We then change \(j\) into a flow \(j'\) on \(g'\) by putting:

\[
j'(\vec{e}') = \sum_{\vec{e} \in \vec{E}(g)} j(\vec{e}) 1_{\vec{e}' \in \phi(\vec{e})}.
\]

It is straightforward to see that \(j'\) is a unit flow from \(\phi(x_{in})\) to \(\infty\). Let us now compute its
energy:

\[ E'(j') \leq \text{Cst} \sum_{e'} j'(e')^2 \]

\[ \leq \text{Cst} \sum_{e'} \left( \sum_e j(e) \mathbf{1}_{e' \in \phi(e)} \right)^2 \]

\[ \leq \text{Cauchy–Schwarz} \sum_{e'} \sum_e j(e)^2 \left( \sum_e \mathbf{1}_{e' \in \phi(e)} \right) \]

\[ \leq \text{see below} \sum_e j(e)^2 < \infty. \]

We have used the fact that there exists \( M \) a number (depending on the constants involved in the quasi-isometry and the maximal degrees in the graphs) such that for any \( e'' \) the total number of oriented edges \( e \) whose “image” \( \phi(e) \) passes through \( e'' \) is bounded by \( M \). This fact is left as an exercise for the reader.
Part II:

One dimensional random walks

This part is devoted to the study of the following object:

**Definition 2.2** (one-dimensional random walk). Let $\mu$ be a probability distribution on $\mathbb{R}$ and consider $X_1, X_2, \ldots$ i.i.d. copies of law $\mu$ which we see as the increments of the process $(S)$ on $\mathbb{R}$ defined as follows: $S_0 = 0$ and for $n \geq 1$

$$S_n = X_1 + \cdots + X_n.$$ 

We say that $(S)$ is a one-dimensional random walk with step distribution $\mu$ (or one-dimensional random walk for short).

![Figure 2.2: Two samples of one-dimensional random walks with different step distributions. The first one seems continuous at large scales whereas the second one displays macroscopic jumps.](image)

The behavior of one-dimensional random walks (recurrence, transience, oscillations...) depends on the step distribution $\mu$ in a non-trivial way as we will see. We will also develop the fluctuation theory for such walks which studies the return times and entrance heights in half-spaces. This knowledge (especially in the case of skip-free random walks) will later be very useful when random walks appear in the study of random graphs and random trees. The interested reader should consult [10, Chapter XII] from which much of the material of this chapter is taken.
In this chapter we fix a law $\mu$ on $\mathbb{R}$ whose support is not included in $\mathbb{R}^+$ nor in $\mathbb{R}^-$ and study the one-dimensional random walk $(S)$ with i.i.d. increments $(X_i)$ following this step distribution. We refer to [24, Chapter II] or [8, Chapter 8] for more details.

3.1 Background and recurrence

3.1.1 Lattice walks

**Definition 3.1.** We say that the walk is lattice if for some $c > 0$ we have $\mathbb{P}(X_1 \in c\mathbb{Z}) = 1$.

Remark that when $(S)$ is lattice we have $S_i \in c\mathbb{Z}$ almost surely for every $i \geq 0$. We will usually suppose that we have $c = 1$ and that gcd(Supp($\mu$)) = 1 so that $(S)$ induces an irreducible aperiodic Markov chain on $\mathbb{Z}$. The prototype of such walk is the simple symmetric random walk on $\mathbb{Z}$ where $\mu = \frac{1}{2}(\delta_1 + \delta_{-1})$. When the walk is non lattice (recall that $\mu$ is supported neither $\mathbb{R}^+$ nor by $\mathbb{R}^-$) then any real is accessible:

**Proposition 3.1.** If the walk is non lattice then

$$\forall x \in \mathbb{R}, \forall \varepsilon > 0, \exists n \geq 0 \quad \mathbb{P}(S_n \in [x \pm \varepsilon]) > 0.$$ 

**Proof.** We consider the topological support of $\mu$ defined as Supp($\mu$) = \{x $\in$ $\mathbb{R}$ : $\forall \varepsilon > 0, \mu([x - \varepsilon, x + \varepsilon]) > 0$\}. Our goal is to show that $A = \bigcup_{n \geq 0} n \cdot$ Supp($\mu$) is dense in $\mathbb{R}$ where $k \cdot E$ is the $k$th sum set $E + E + \cdots + E$. Since $\mu$ is non lattice the group generated by Supp($\mu$) is not discrete, hence it is dense in $\mathbb{R}$. We conclude using the fact that if $A \not\subset \mathbb{R}_+$ nor $\mathbb{R}_-$ and that the group generated by $A$ is dense in $\mathbb{R}$ then the semi group generated by $A$ is also dense in $\mathbb{R}$ (exercise).

When the walk has a step distribution which has no atoms (it is diffuse) then almost surely the values taken by the random walk are pairwise distinct and in particular $S_i \neq 0$ except for $i = 0$. To see this, fix $0 \leq i < j$ and write

$$\mathbb{P}(S_i = S_j) = \mathbb{P}(X_{i+1} + X_{i+2} + \cdots + X_j = 0) = \mathbb{P}(-X_j = X_{i+1} + X_{i+2} + \cdots + X_{j-1}),$$

but since $X_j$ is independent of $X_{i+1} + X_{i+2} + \cdots + X_{j-1}$ and has no atoms this probability is equal to 0. One can then sum over all countable pairs of $i \neq j \geq 0$ to get the claim.
3.1.2 Markov property and $0/1$ laws

Before starting with the main course of this chapter, let us recall the very useful Markov property which takes a nice form in our setup: as usual $\mathcal{F}_n = \sigma(X_1, \ldots, X_n)$ is the natural filtration generated by the walk $(S)$ up to time $n$ and a stopping time is a random variable $\tau \in \{0, 1, 2, \ldots\} \cup \{\infty\}$ such that for each $n \geq 0$ the event $\{\tau = n\}$ is measurable with respect to $\mathcal{F}_n$. In our context the (strong) Markov property can be rephrased as:

**Proposition 3.2.** If $\tau$ is a stopping time such that $\tau < \infty$ almost surely then the process $(S^{(\tau)}_n)_{n \geq 0} = (S_{\tau+n} - S_\tau)_{n \geq 0}$ is independent of $(S_n)_{0 \leq n \leq \tau}$ and is distributed as the initial walk $(S_n)_{n \geq 0}$.

**Proof.** Let $f, g$ be two positive measurable functions and let us compute

$$
\mathbb{E} \left[ f \left( (S_n)_{0 \leq n \leq \tau} \right) g \left( (S_n^{(\tau)})_{n \geq 0} \right) \right] = \sum_{k=0}^{\infty} \mathbb{E} \left[ 1_{\tau = k} f \left( (S_n)_{0 \leq n \leq k} \right) g \left( (S_n^{(k)})_{n \geq 0} \right) \right]
$$

$$
= \text{indep.} \sum_{k=0}^{\infty} \mathbb{E} \left[ 1_{\tau = k} f \left( (S_n)_{0 \leq n \leq k} \right) \right] \mathbb{E} \left[ g \left( (S_n^{(k)})_{n \geq 0} \right) \right]
$$

$$
= \text{stat.} \sum_{k=0}^{\infty} \mathbb{E} \left[ 1_{\tau = k} f \left( (S_n)_{0 \leq n \leq k} \right) \right] \mathbb{E} \left[ g \left( (S_n)_{n \geq 0} \right) \right]
$$

$$
= \mathbb{E} \left[ f \left( (S_n)_{0 \leq n \leq \tau} \right) \right] \mathbb{E} \left[ g \left( (S_n)_{n \geq 0} \right) \right],
$$

and this proves the proposition. \qed

In the study of random walks, one often uses $0 – 1$ laws when dealing with asymptotic events such as $\{S_n \to \infty\}$. The most well-known of such laws is Kolmogorov $0 – 1$ law which states that if $(X_i)_{i \geq 0}$ are independent random variables (not necessarily identically distributed), then any event $\mathcal{A}$ measurable with respect to $\sigma(X_i : i \geq 0)$ and which is independent of $(X_1, \ldots, X_{n_0})$ for any $n_0$ has measure $\mathbb{P}(\mathcal{A}) \in \{0, 1\}$. We give here a stronger version of Kolmogorov$^1$ $0 – 1$ law in the case of i.i.d. increments which has many applications in the random walk setting:

**Theorem 3.3 (Hewitt–Savage exchangeable $0 – 1$ law)**

Let $(X_i)_{i \geq 1}$ be a sequence of independent and identically distributed random variables. Suppose that $\mathcal{A}$ is a measurable event with respect to $\sigma(X_i : i \geq 1)$ which is invariant (up to negligible events) by any finite permutation of the $(X_i : i \geq 1)$. Then $\mathbb{P}(\mathcal{A}) \in \{0, 1\}$.

**Proof.** Let $\mathcal{A} \in \sigma(X_i : i \geq 1)$ be invariant by finite permutations of the $X_i$. By standard measure-theory arguments one can approximate $\mathcal{A}$ by a sequence of events $\mathcal{A}_n \in \sigma(X_1, \ldots, X_n)$ in the sense that

$$
\mathbb{P}(\mathcal{A} \Delta \mathcal{A}_n) \xrightarrow{n \to \infty} 0.
$$

$^1$ Andreĭ Nikolaevitch Kolmogorov 1903–1987
We write \( A_n = \{(X_1, \ldots, X_n) \in B_n\} \) where \( B_n \) is a measurable event of \( X^n \) where \( X \) is the target space of our random variables. We now consider the function \( \psi_n \) acting on measurable events which consists in exchanging \( X_1, \ldots, X_n \) with \( X_{n+1}, \ldots, X_{2n} \). In particular we have \( \psi_n(A_n) = \{(X_{n+1}, \ldots, X_{2n}) \in B_n\} \) and by our assumptions \( \psi_n(A) = A \) up to null events. Since the \( X_i \) are i.i.d. we have \( P(\psi_n(E)) = P(E) \) for any event \( E \). Using this we have

\[
0 \leftarrow \lim_{n \to \infty} P(A \Delta A_n) = P(\psi_n(A \Delta A_n)) = P(\psi_n(A) \Delta \psi_n(A_n)) = P(A \Delta \psi_n(A_n)).
\]

We deduce that \( A \) is both very well approximated by \( A_n \) but also by \( \psi_n(A_n) \). Since the last two events are independent we deduce that \( P(A) \in \{0, 1\} \) because

\[
P(A) = \lim_{n \to \infty} P(A_n \cap \psi_n(A_n)) = \lim_{n \to \infty} P(A_n)P(\psi_n(A_n)) = \lim_{n \to \infty} P(A_n)^2 = P(A)^2. \]

**Example 3.1.** If \( A \in \mathbb{R} \) is a measurable subset we write

\[
\mathcal{I}_A := \sum_{n=0}^{\infty} 1_{S_n \in A}.
\]

Then the commutativity of \( \mathbb{R} \) (sic) shows that the event \( \{\mathcal{I}_A = \infty\} \) is invariant under finite permutations of the \( X_i \)'s (indeed any finite permutation leaves \( S_n \) invariant for large \( n \)): hence it has probability 0 or 1. Notice that this cannot be deduced directly from Kolmogorov’s 0 − 1 law. (This observation is valid in any Abelian group).

### 3.1.3 Recurrence

In the case of lattice random walks, or random walks on graphs (see Part I), or even irreducible Markov chain on a countable state space, the concept of recurrence is clear: we say that \((S)\) is recurrent if it comes back infinitely often to 0 with probability one. Our first task is to extend this notion in the context of general random walks on \( \mathbb{R} \) where the random walk may not even come back exactly at 0 once.

**Definition-Proposition 3.1.** The random walk \((S)\) is said to be recurrent if one of the following equivalent conditions holds:

1. For every \( \varepsilon > 0 \) we have \( P(\exists n \geq 1 : |S_n| < \varepsilon) = 1 \),
2. \( P(|S_n| < 1 \text{ for infinitely many } n) = 1 \),
3. \( P(|S_n| \to \infty) = 0 \),
4. \( E\left[\sum_{n=0}^{\infty} 1_{|S_n| < 1}\right] = \infty \).

Otherwise the walk is said to be transient and the complementary events hold.

Notice that in the case of random walks on \( \mathbb{Z} \), or more generally the lattice case (even in the case of any irreducible Markov chain on \( \mathbb{Z} \)), the above conditions reduce to the well-know equivalences:

\[
P(|S_n| \to \infty) = 0 \iff P(\exists n \geq 1 : S_n = 0) = 1 \iff E[\#\text{returns to 0}] = \infty.
\]
Proof. We consider only the non-lattice case. Let us suppose \((i)\) and prove \((ii)\). Fix \(\varepsilon > 0\) small and let \(\tau_\varepsilon = \inf\{k \geq 1 : |S_0 - S_k| \leq \varepsilon\}\) be the first return of the walk inside \([-\varepsilon, \varepsilon]\). By \((i)\) we know that the stopping time \(\tau_\varepsilon\) is almost surely finite. If we define by induction

\[
\tau_\varepsilon^{(i)} = \inf\{k > \tau_\varepsilon^{(i-1)} : |S_k - S_{\tau_\varepsilon^{(i-1)}}| \leq \varepsilon\}
\]

then an application of the strong Markov property shows that \(\tau_\varepsilon^{(i)}\) is finite almost surely for every \(i \geq 1\). Now if \(k < \frac{1}{\varepsilon}\) it is clear that \(|S_{\tau_\varepsilon^{(i)}}| \leq k\varepsilon < 1\) and hence \(#\{n \geq 0 : |S_n| < 1\}\) is almost surely larger than \(\varepsilon^{-1}\). Since this holds for any \(\varepsilon > 0\) we deduce that \(#\{n \geq 0 : |S_n| < 1\} = \infty\) almost surely as desired in \((ii)\).

The implication \((ii) \Rightarrow (iii)\) is clear.

\((iii) \Rightarrow (i)\). We will prove first that for any non trivial interval \((a, b)\) the event \(\{I_{(a,b)} = \infty\}\) is equal to \(\{I_{(-1,1)} = \infty\}\) up to negligible events (recall the notation \((3.1)\)). To see this denote the successive returns times of \(S\) in \((-1, 1)\) by \(\tau(0) = 0\) and \(\tau(k) = \inf\{n > \tau(k-1) : S_n \in (-1,1)\}\). We then claim (Exercise!) that using Proposition \(3.1\) one can find \(n_0 \geq 1\) and \(\varepsilon > 0\) such that irrespectively of \(x \in (-1,1)\) we have \(P(x + S_n_0 \in (a, b)) > \varepsilon\). Using this and the strong Markov property, it is easy to see by standard Markov chain arguments that the events \(\{I_{(-1,1)} = \infty\}\), \(\{\tau(k) < \infty, \forall k \geq 0\}\) and \(\{I_{(a,b)} = \infty\}\) coincide up to a null event. By the \(0 - 1\) law established in Example \(3.1\) we thus deduce that either

\[
\text{a.s. } \forall a \neq b \in \mathbb{Q} \text{ we have } I_{(a,b)} < \infty \quad \text{or} \quad \forall a \neq b \in \mathbb{Q} \text{ we have } I_{(a,b)} = \infty. \quad (3.2)
\]

Now suppose \((iii)\). Since \(|S_n|\) does not diverge with probability 1, this means that there exists a (random) value \(A\) such that \(S_n \in [-A, A]\) for infinitely many \(n\). This clearly implies that we are in the second option in the last display and in particular \(I_{(-\varepsilon, \varepsilon)} = \infty\) almost surely for any \(\varepsilon > 0\).

Since clearly \((ii) \Rightarrow (iv)\) it remains to prove \((iv) \Rightarrow (i)\). Suppose \((iv)\) and assume non \((i)\) by contradiction. This means that for some \(\varepsilon > 0\) we have \(P(\forall n \geq 1 : |S_n| \geq \varepsilon) > \varepsilon\). By considering the successive return times to \((-\varepsilon/2, \varepsilon/2)\), the strong Markov property shows that

\[
P\left(\sum_{i \geq 0} 1_{|S_i| < \varepsilon/2} \geq k\right) = P(I_{(-\varepsilon/2, \varepsilon/2)} \geq k) \leq (1 - \varepsilon)^k.
\]

We deduce that \(E[I_{(-\varepsilon/2, \varepsilon/2)}] < \infty\). Now if \((a, b)\) is any interval of length \(\varepsilon/2\), by applying the Markov property at the hitting time \(\tau_{(a,b)}\) of \((a, b)\) we get that

\[
E[I_{(a,b)}] \leq P(\tau_{(a,b)} < \infty) E[I_{(-\varepsilon/2, \varepsilon/2)}].
\]

Since \(I_{(-1,1)}\) is less than the sum of roughly \(2/\varepsilon\) terms \(I_{(a_i, b_i)}\) where \((-1,1) \subset \cup_{i}(a_i, b_i)\) and \(|a_i - b_i| \leq \varepsilon/2\) we reach a contradiction since this implies that \(I_{(-1,1)}\) is of finite expectation. \(\square\)

The above proof shows in fact that \((S)\) is recurrent if and only

\[
\exists a \neq b \in \mathbb{R}, \quad E[I_{(a,b)}] = \infty \iff \forall a \neq b \in \mathbb{R}, \quad I_{(a,b)} = \infty.
\]
Remark 3.1. We will furnish later a criterion for recurrence based on the Fourier transform of the step distribution, see the Chung–Fuchs Theorem 8.3.

Exercise 3.1. Show that \((S_n)_{n \geq 0}\) is recurrent if and only if \((S_{2n})_{n \geq 0}\) is recurrent.

3.2 Oscillation and drift

In the last section we focused on the dichotomy between recurrence/transience. We now further split transient walks into two finer categories: oscillating random walks and drifting random walks.

3.2.1 Dichotomy

**Definition-Proposition 3.2.** A (non-trivial) one-dimensional random walk \((S)\) falls into exactly one of the three categories:

(i) Either \(S_n \to \infty\) a.s. as \(n \to \infty\) in which case \((S)\) is said to drift towards \(\infty\),

(ii) Or \(S_n \to -\infty\) a.s. as \(n \to \infty\) in which case \((S)\) is said to drift towards \(-\infty\),

(iii) Or \((S)\) oscillates i.e. \(\limsup_{n \to \infty} S_n = +\infty\) and \(\liminf_{n \to \infty} S_n = -\infty\) almost surely.

**Proof.** Note that our background assumption on \(\mu\) forces \(\mu \neq \delta_0\) for which none of the above cases apply. In the lattice case, this proposition is well known. Let us suppose that we are in the non-lattice case. Each of the events defining points (i) – (ii) – (iii) are independent of the values of the first few values of the increments. By Kolmogorov’s 0–1 law they thus appear with probability 0 or 1. Let us suppose that we are in none of the above cases. With the notation of the proof Definition-Proposition 3.1 this means that \(\bigcup_{k \geq 1} \{I_{(-k,k)} = \infty\}\) is of full probability and so we are in the second alternative of (3.2). This is clearly a contradiction because then the range would be dense in \(\mathbb{R}\).

**Example 3.2.**

- A recurrent walk automatically oscillates.
- However, a transient walk does not necessarily drifts towards \(+\infty\) or \(-\infty\) (see below).
- A random walk whose increments are symmetric necessarily oscillates.
3.2.2 Ladder variables

**Definition 3.2 (Ladder heights and epochs).** We define by induction \( T^>_0 = T^<_0 = T^>_0 = T^<_0 = 0 \) as well as \( H^>_0 = H^<_0 = H^>_0 = H^<_0 = 0 \) and for \( i \geq 1 \) we put

\[
\begin{align*}
T^>_i &= \inf \{ k > T^>_i-1 : S_k > H^>_i-1 \} \quad \text{and} \quad H^>_i = S_{T^>_i}, \\
T^>_i &= \inf \{ k > T^>_i-1 : S_k \geq H^>_i-1 \} \quad \text{and} \quad H^>_i = S_{T^>_i}, \\
T^<_i &= \inf \{ k > T^<_i-1 : S_k < H^<_i-1 \} \quad \text{and} \quad H^<_i = S_{T^<_i}, \\
T^<_i &= \inf \{ k > T^<_i-1 : S_k \leq H^<_i-1 \} \quad \text{and} \quad H^<_i = S_{T^<_i}.
\end{align*}
\]

If \( T^*_i \) is not defined (i.e. we take the infimum over the empty set) then we put \( T^*_j = H^*_j = \pm \infty \) for all \( j \geq i \). The variables \( (T^>_i, H^>_i) \) (resp. \( (T^<_i, H^<_i) \)) are called the strict/weak ascending (resp. descending) ladder epochs. The associated \( H \) process are called the (strict/weak ascending/descending) ladder heights.

**Remark 3.2.** When the walk \( (S) \) has continuous increments, since almost surely \( S \) does not take twice the same value the weak and strict ladder variables are the same.

In the following we write \( H \) and \( T \) generically for one of the four couples

\[ (T^>_i, H^>_i), (T^>_i, H^>_i), (T^<_i, H^<_i) \) or \( (T^<_i, H^<_i) \).

The ladder epochs are clearly stopping times for the natural filtration generated by the walk and the strong Markov property shows that \( N \) defined as \( \inf \{ i \geq 0 : T_i = \infty \} \) is a geometric

![Figure 3.1: Illustration of the definition of the ladder heights and epochs.](image-url)
random variable with distribution

\[ P(N = k) = P(T_1 = \infty)P(T_1 < \infty)^{k-1}, \]

and that conditionally on \( N \) the random variables \((T_{i+1} - T_i), (H_{i+1} - H_i)\)\(0 \leq i \leq N-1 \) are i.i.d. with law \((T_1, H_1)\) conditioned on \( T_1 < \infty \). Combining these observations with Definition-Proposition 3.2 we deduce a characterization of drift/oscillation in terms of the ladder epochs:

**Proposition 3.4.** The walk \((S)\) drifts towards \(+\infty\) if and only if \( P(T_1^\leq = \infty) > 0 \) and \( P(T_1^\geq = \infty) = 0 \). The walk \((S)\) oscillates if and only if \( P(T_1^\leq = \infty) = P(T_1^\geq = \infty) = 0 \).

### 3.3 Walks with finite mean

In this section we examine the particular case when \( E[|X|] < \infty \) and show in particular that the walk is recurrent whenever it is centered, otherwise it is transient and drifts.

#### 3.3.1 Recurrence/transience

**Theorem 3.5**

Suppose \( E[|X_1|] < \infty \) then

(i) If \( E[X_1] \neq 0 \) then \((S)\) is transient and drifts,

(ii) otherwise if \( E[X_1] = 0 \) then \((S)\) is recurrent.

**Proof.** The first point (i) is easy since by the strong law of large numbers we have \( n^{-1}S_n \to E[X_1] \) almost surely: when \( E[X_1] \neq 0 \) this automatically implies that \(|S_n| \to \infty\) and so \((S)\) is transient by Definition-Proposition 3.1 and drifts towards \( \pm \infty \) depending on the sign of \( E[X] \).

In the second case we still use the law of large numbers to deduce that \( S_n/n \to 0 \) almost surely as \( n \to \infty \). This in particular implies that for any \( \varepsilon > 0 \) we have \(|S_n| \leq \varepsilon n\) eventually and so for \( n \) large enough

\[
\sum_{i=0}^{\infty} 1_{|S_i| \leq n} \geq n \quad \text{so that} \quad E \left[ \sum_{i=0}^{\infty} 1_{|S_i| \leq n} \right] \geq n/2.
\]

(3.3)

We claim that this inequality is not compatible with transience. Indeed, according to Definition-Proposition 3.1, if the walk \((S)\) is transient then for some constant \( C > 0 \) we have

\[
E \left[ \sum_{i=0}^{\infty} 1_{|S_i| < 1} \right] \leq C.
\]

If \( x \in \mathbb{R} \), applying the strong Markov property at the first time \( \tau \) we have \( S_{\tau} \in [x, x+1] \) we deduce that

\[
E \left[ \sum_{i=0}^{\infty} 1_{S_i \in [x, x+1]} \right] \leq P(\tau < \infty) E \left[ \sum_{i=0}^{\infty} 1_{|S_i| < 1} \right] \leq C.
\]

40
Dividing the interval \([-\varepsilon n, \varepsilon n]\) into at most \(2\varepsilon n + 2\) interval of length at most 1 and applying the above inequality we would deduce that \(E \left[ \sum_{i=0}^{\infty} 1_{|S_i| \leq \varepsilon n} \right] \leq (2\varepsilon n + 2)C\) which contradicts (3.3) for \(\varepsilon > 0\) small enough. Hence the walk cannot be transient.

\[\square\]

**Exercise 3.2.** Let \((S_n)_{n \geq 0}\) be a one-dimensional random walk with step distribution \(\mu\) on \(\mathbb{R}\).

1. Show that if \(n^{-1} \cdot S_n \xrightarrow{p} 0\) then \((S)\) is recurrent.
2. Using the Cauchy law (Section 3.4) show that the converse is false.

### 3.3.2 Wald’s equality

**Theorem 3.6 (Wald equality)**

Suppose \(E[|X_1|] < \infty\). Let \(\tau\) be a stopping time with finite expectation. Then we have

\[E[\tau] \cdot E[X_1] = E[X_\tau].\]

**Proof with martingales.** We present a first proof based on martingale techniques. If we denote by \(m\) the mean of \(X_1\) then clearly the process \((S_n - nm)_{n \geq 0}\) is a martingale for the canonical filtration \(F_n = \sigma(X_1, \ldots, X_n)\). By the optional sampling theorem we then deduce that

\[E[S_{n \wedge \tau}] = mE[n \wedge \tau].\]

(3.4)

Since \(\tau\) is almost surely finite by Corollary 4.2, we can let \(n \to \infty\) and get by monotone convergence that the right hand side tends to \(E[\tau]\). However, to deduce that the left hand side also converges towards \(E[S_\tau]\) one would need a domination... To get this just remark that for all \(n\) we have

\[|S_{n \wedge \tau}| \leq \sum_{i=1}^{\tau} |X_i|,
\]

and the last variable has a finite expectation equal to \(E[\tau]E[|X|] < \infty\) by a standard exercise. On can then use this domination to prove convergence of the left-hand side in (3.4).

\[\square\]

**Proof with law of large numbers.** We give a second proof based on the law of large numbers. The idea is to iterate the stopping rule. Let \(\tau = \tau_1 \leq \tau_2 \leq \tau_3 \leq \ldots\) be the successive stopping times obtained formally as

\[\tau_{i+1} = \tau_{i+1}(S_{n \geq 0}) = \tau_i((S_n)_{n \geq 0}) + \tau((S_{n+\tau_i}(S_n)_{n \geq 0})_{n \geq 0}),\]

for \(i \geq 1\). In particular \((\tau_{i+1} - \tau_i; S_{\tau_{i+1}} - S_{\tau_i})_{i \geq 0}\) are i.i.d. of law \((\tau, X_\tau)\). By the law of large numbers (we suppose here that \(\tau \neq 0\) otherwise the result is trivial) we get that

\[\frac{S_{\tau_i}}{\tau_i} \xrightarrow{a.s.} \frac{1}{\tau} E[X_1].\]
On the other hand since $\tau$ has finite expectation by assumption, applying once more the law of large numbers we deduce that

$$\frac{S_{\tau_i}}{i} = \frac{S_{\tau_i}}{\tau_i} \cdot \frac{\tau_i}{i} \xrightarrow{a.s.} i \to \infty E[X_1] \cdot E[\tau].$$

We then use the reciprocal of the law of large numbers (see Exercise 3.3) to deduce that $S_{\tau}$ has finite expectation and equal to $E[\tau] \cdot E[X_1]$ as claimed by Wald.

**Exercise 3.3** (Converse to the strong law of large numbers). Let $(X_i)_{i \geq 0}$ be i.i.d. real variables and suppose that for some constant $c \in \mathbb{R}$ we have

$$X_1 + \cdots + X_n \xrightarrow{n \to \infty} c.$$ 

The goal is to show that $X_i$ have a finite first moment and $E[X_1] = c$. For this we argue by contradiction and suppose that $E[|X|] = \infty$.

(i) Show that $\sum_{n \geq 1} P(|X| > n) = \infty$.

(ii) Deduce that $|X_n| > n$ for infinitely many $n$’s.

(iii) Conclude.

(iv) By considering increments having law $P(X = k) = P(X = -k) \sim c/(k^2 \log k)$ for some $c > 0$, show that the converse of the weak law of large numbers does not hold.

### 3.4 Examples

We illustrate in this section the concept of recurrence/transience and oscillation/drift in the case when the step distribution has a stable law (either the Gaussian, Lévy or Cauchy distribution) or when it is heavy-tailed (and regular varying).

#### 3.4.1 Stable laws

**Gaussian law.** First, let us suppose that $\mu(dx) = \frac{dx}{\sqrt{2\pi}} e^{-x^2/2}$ is the standard Gaussian distribution on $\mathbb{R}$. In this case, since $\mu$ has a first moment and is centered, one can apply Theorem 3.5 and deduce that the associated walk is recurrent (and thus oscillates). Let us deduce this via another route. A well-know property of Gaussian distribution shows that

$$S_n = X_1 + \cdots + X_n \xrightarrow{(d)} \sqrt{n}X_1.$$
This is called the so-called stability property of the Gaussian law of index 2 (appearing in \( \sqrt{n} = n^{1/2} \)). In particular the last display shows that

\[
\sum_{n \geq 1} \mathbb{P}(|S_n| < 1) = \sum_{n \geq 1} \mathbb{P}(|X_1| \leq \frac{1}{\sqrt{n}}) \sim \frac{1}{\sqrt{2\pi n}}.
\]

Hence the last series is infinite and so the walk is recurrent by Definition-Proposition 3.1. One could of course have deduced the same result using the criterion 8.3 together with the well-known fact that the Fourier transform of \( \mu \) is equal to \( \hat{\mu}(t) = e^{-t^2/2} \) for all \( t \in \mathbb{R} \). Let us generalize these approaches to other interesting laws.

**Lévy law.** We now consider \( \mu(dx) = \frac{1}{\sqrt{2\pi x^3}}e^{-\frac{1}{2x}}dx1_{x>0} \) called the standard Lévy\(^4\). This distribution appears as the first hitting time of \(-1\) by a standard Brownian real motion \((B_t)_{t \geq 0}\) starting from 0 (reflection principle). Using the strong Markov property of the Brownian motion, if \( X_1, \ldots, X_n \) are i.i.d. of law \( \mu \) then \( X_1 + \cdots + X_n \) is equal in law to the first hitting time of \(-n\) by \( (B_t)\). Combining this observation with the scaling property of \( B \) we deduce that

\[
S_n = X_1 + \cdots + X_n \overset{(d)}{=} n^2X_1,
\]

and we say that \( \mu \) is a stable law with index \( 1/2 \) (the last display can also be seen by a direct calculation). In particular the walk \((S)\) is transient since

\[
\sum_{n \geq 1} \mathbb{P}(|S_n| < 1) = \sum_{n \geq 1} \mathbb{P}(|X_1| \leq \frac{1}{n^2}) < \infty.
\]

This is not surprising since \( \mu \) is supported on \( \mathbb{R}_+ \) and so summing positive increments yields \((S)\) to drift to infinity. But the last calculation is more surprising once we realized it is also valid if we consider for \( \mu \) the law of \( X + cX' \) where \( X \) and \( X' \) are independent copies of standard Lévy law! In particular if \( c \) is negative then \( \mathbb{P}(S_n > 0) = \mathbb{P}(X_1 > 0) \in (0,1) \) and so the walk cannot drift. This gives an example of a transient yet oscillating random walk.

**Exercise 3.4.** Compute the Laplace transform \( \mathcal{L}(\mu)(t) = \int \mu(dx)e^{-tx} \) for \( t > 0 \).

**Cauchy walk.** Our last example is when \( \mu(dx) = \frac{dx}{\pi(1+x^2)} \) is the standard Cauchy\(^5\) distribution on \( \mathbb{R} \). This is again an instance of a stable random variable (here of index 1) since it is well known that if \( X_1, \ldots, X_n \) are i.i.d. copies of law \( \mu \) then

\[
S_n = X_1 + \cdots + X_n \overset{(d)}{=} nX_1.
\]

---

5. Augustin Louis, baron Cauchy 1789–1857
One way to see this is to realize $X_1$ as the $x$-value of a standard two dimensional Brownian motion started from $(0, 0)$ and stopped at the first hitting time of the line $y = -1$. Performing the same calculation as above we realize that

$$\sum_{n \geq 1} P(|S_n| < 1) = \sum_{n \geq 1} P(|X_1| \leq \frac{1}{n}) = \infty,$$

and so $(S)$ is an example of a recurrent random walk even though its increment does not admit a first moment! It may also be surprising to the reader that the walk $(S_n + cn)_{n \geq 0}$ is also recurrent for any value of $c \in \mathbb{R}$ by the same argument! Another way to prove recurrence for the last walk is to apply the Fourier criterion of Theorem 8.3 provided the next exercise is solved:

**Exercise 3.5.** Show that the Fourier transform $\hat{\mu}$ of the standard Cauchy distribution is given by $\hat{\mu}(t) = e^{-|t|}$ for $t \in \mathbb{R}$.

As we said, the Gaussian, Lévy and Cauchy distributions are particular instances of stable distributions. We just give the definition since their study would need a full M2 course following the steps of Paul Lévy.

**Definition 3.3.** A stable distribution $\mu$ is a law on $\mathbb{R}$ such that for all $n \geq 1$ if $X_1, X_2, \ldots, X_n$ are $n$ independent copies of law $\mu$ then for some $A_n, B_n \in \mathbb{R}$ we have

$$X_1 + \cdots + X_n \xrightarrow{(d)} A_n \cdot X + B_n.$$

It turns out that necessarily $A_n = n^{1/\alpha}$ for some $\alpha \in (0, 2]$ which is called the index of stability of the law. The only stable laws with “explicit” densities are the Gaussian laws ($\alpha = 2$), the Lévy laws ($\alpha = \frac{1}{2}$) and the Cauchy laws ($\alpha = 1$).

### 3.4.2 Heavy-tailed random walks

Here is an example of a random walk with “heavy tails” which is transient and yet oscillates:

**Proposition 3.7.** Let $\mu$ be a step distribution on $\mathbb{Z}$ such that $\mu_k = \mu_{-k} \sim k^{-\alpha}$ as $k \to \infty$ for $\alpha \in (1, 2)$. In particular $\mu$ has no first moment. Then the associated random walk $(S)$ is transient and yet oscillates.

**Remark 3.3.** If $\alpha > 2$, the walk $(S)$ is centered and so by Theorem 3.5. The critical case $\alpha = 2$ where the step distribution has Cauchy-type tail is more delicate: the walk is recurrent (see Exercise 3.2).

**Proof.** Since $(S)$ is a symmetric random walk, it cannot drift and must oscillate. We just need to show that $(S)$ is transient e.g.

$$\sum_{n \geq 0} P(S_n = 0) < \infty.$$
The idea is to use the randomness produced by a single big jump of the walk. More precisely, let us introduce the event \( A = \{ \exists 1 \leq i \leq n : |X_i| > n^{1+\varepsilon} \} \) where \( \varepsilon > 0 \) will be chosen small enough later on. We can write

\[
P(S_n = 0) \leq P(A^c) + P(S_n = 0 \mid A).
\]

The first term of the right-hand side is easy to evaluate:

\[
P(A^c) = (1 - P(|X| \geq n^{1+\varepsilon}))^n \approx \exp(-c \cdot n \cdot n(1+\varepsilon)(1-\alpha)) \leq \exp(-n^\delta),
\]

for some \( \delta > 0 \) provided that \( \varepsilon > 0 \) is small enough (we used here the fact that \( 1 < \alpha < 2 \)).

On the other hand, conditionally on \( A \), one can consider the first increment \( |X_{i_0}| \) of \( S \) of absolute value larger than \( n^{1+\varepsilon} \). Clearly, the law \( \nu \) of \( X_{i_0} \) is that of \( X \) conditioned on being of absolute value larger than \( n^{1+\varepsilon} \) and in particular

\[
\forall k \in \mathbb{Z}, \quad \nu(k) = 1_{|k| > n^{1+\varepsilon}} \frac{P(X = k)}{P(|X| > n^{1+\varepsilon})} \leq Cn^{-1-\varepsilon},
\]

for some constant \( C > 0 \) and \( X_{i_0} \) is furthermore independent of all the other increments. Hence we can write

\[
P(S_n = 0 \mid A) = P(X_{i_0} = -(X_1 + \cdots + \widehat{X}_{i_0} + \cdots + X_n) \mid A) \leq \sup_{k \in \mathbb{Z}} \nu(k) \leq Cn^{-1-\varepsilon}.
\]

Gathering-up the pieces, we deduced that \( P(S_n = 0) \leq \exp(-n^\delta) + Cn^{-1-\varepsilon} \) for \( \delta > 0 \) provided that \( \varepsilon > 0 \) is small enough. The implies summability of the series and ensures transience of the walk.

Let us also state without proof a theorem of Shepp\(^6\) which shows that there exists recurrent one-dimensional random walk with arbitrary fat tails (but not regular varying):

**Theorem 3.8 (Shepp [23])**

*For any position function \( \epsilon(x) \) tending to 0 as \( x \to \infty \), there exists a symmetric step distribution \( \mu \) such that \( \mu(\mathbb{R} \setminus [-x, x]) \geq \epsilon(x) \) for any \( x \geq 0 \) and such that the associated random walk \( (S) \) is recurrent.*

More exercises.

**Exercise 3.6 (Sums of random walks).** Let \((S_n)_{n \geq 0}\) and \((S'_n)_{n \geq 0}\) be two independent one-dimensional random walks with independent increments of law \( \mu \) and \( \mu' \) on \( \mathbb{R} \).

1. Give an example where \((S)\) and \((S')\) are transient and yet \((S + S')\) is recurrent.

2. We suppose that \( \mu \) and \( \mu' \) are both symmetric. Show that as soon as \((S)\) or \((S')\) is transient then so is \((S + S')\).

---

\(^6\) Lawrence Alan Shepp 1936–2013
3. Give an example where \((S)\) is recurrent, \((S')\) transient and yet \((S+S')\) is recurrent. (Hint: Use the Cauchy law of Section 3.4).

4. (*) Can we have both \((S)\) and \((S')\) recurrent and \((S+S')\) transient?

**Exercise 3.7 (Subordinated random walks).** Let \((S_n)_{n\geq 0}\) be a one-dimensional random walk with step distribution \(\mu\). Let also \((Y_n)_{n\geq 0}\) be another independent one-dimensional random walk whose step distribution \(\nu\) is supported on \(\{1,2,3,\ldots\}\) and is aperiodic. We form the process

\[ Z_n = S_{Y_n}. \]

1. Show that \((Z)\) is again a one-dimensional random walk with independent increments and characterize its step distribution.

2. Show that if \(\int \nu(dx)x < \infty\) then \(Z\) and \(S\) have the same type (recurrent, transient, oscillating, drifting towards \(\pm\infty\)).

3. Let \(\nu\) be the return time to \((0,0)\) of the simple random walk on \(\mathbb{Z}^2\). Using Theorem 8.5 show that for any \(\mu\) the walk \((Z)\) is transient.

4. (*) Can we find \((\mu,\nu)\) so that \((S)\) oscillates but \((Z)\) drifts?
In this chapter we still consider a one-dimensional random walk $(S)$ based on i.i.d. increments of law $\mu$ (whose support is not contained in $\mathbb{R}_+$ nor $\mathbb{R}_-\)). The goal now is to get information on the distribution of the ladder processes and reciprocally get information on the walk from the ladder processes. We refer to [10, Chapter XII] or [8, Section 8.4] for details.

### 4.1 Duality and applications

We begin with a surprisingly simple but important observation called duality.

**Proposition 4.1 (Duality).** For each fixed $n \geq 0$, we have the following equality in distribution

\[
(0 = S_0, S_1, \ldots, S_n) \overset{(d)}{=} (S_n - S_n, S_n - S_{n-1}, S_n - S_{n-2}, \ldots, S_n - S_1, S_n).
\]

**Proof.** It suffices to notice that the increments of the walk $(S_n - S_{n-1}, S_n - S_{n-2}, \ldots, S_n - S_1, 0)$ are just given by $(X_n, X_{n-1}, \ldots, X_1)$ which obviously has the same law as $(X_1, \ldots, X_n)$ since the $(X_i)_{i \geq 1}$ are i.i.d. hence exchangeable.

**Exercise 4.1.** Let $(S)$ be a one-dimensional random walk drifting towards $-\infty$. Using duality show that $S_n - \inf_{0 \leq k \leq n} S_k$ converges in distribution as $n \to \infty$ towards $\sup_{k \geq 0} S_k$. 47
This innocent proposition enables us to connect the strict descending ladder variables to the weak ascending ones. Indeed, notice (on a drawing) that for any \( n \geq 0 \)

\[
\mathbb{P}(T_1^\leq > n) = \mathbb{P}(S_0 = 0, S_1 \geq 0, \ldots, S_n \geq 0)
\]

\[
= \mathbb{P}(S_n - S_n = 0, S_n - S_{n-1} \geq 0, \ldots, S_n \geq 0)
\]

\[
= \mathbb{P}(S_n \geq S_{n-1}, S_n \geq S_{n-2}, \ldots, S_n \geq S_0) = \mathbb{P}(n \text{ is a weak ladder epoch}).
\]

Summing over \( n \geq 0 \) we deduce that

\[
\sum_{n \geq 0} \mathbb{P}(T_1^\leq > n) = \mathbb{E}[T_1^\leq]
\]

\[
= \mathbb{E}[\text{number of weak ascending finite ladder epochs}]
\]

\[
= \frac{1}{\mathbb{P}(T_1^\geq = \infty)}, \tag{4.1}
\]

because the total number of weak ascending finite ladder epochs follows a geometric distribution with success parameter \( \mathbb{P}(T_1^\geq = \infty) \). We similarly establish that \( \mathbb{E}[T_1^\geq] = 1/\mathbb{P}(T_1^\geq = \infty) \). From these observations we conclude:

**Corollary 4.2.** We are in one of the three categories:

- **Either** \((S)\) **drifts towards** \(+\infty\) **in which case we have**
  \[
  \mathbb{P}(T_1^\leq = \infty) > 0, \quad \mathbb{P}(T_1^\geq = \infty) > 0, \quad \mathbb{E}[T_1^\leq] < \infty, \quad \mathbb{E}[T_1^\geq] < \infty,
  \]

- **Either** \((S)\) **drifts towards** \(-\infty\) **in which case we have**
  \[
  \mathbb{P}(T_1^\geq = \infty) > 0, \quad \mathbb{P}(T_1^\leq = \infty) > 0, \quad \mathbb{E}[T_1^\leq] < \infty, \quad \mathbb{E}[T_1^\geq] < \infty,
  \]

- **Or** \((S)\) **oscillates then the ladder epochs are finite but**
  \[
  \mathbb{E}[T_1^\geq] = \mathbb{E}[T_1^\leq] = \mathbb{E}[T_1^\leq] = \mathbb{E}[T_1^\geq] = \infty.
  \]

**Remark 4.1.** The last corollary shows that for an oscillating random walk, although the walk will visit \( \mathbb{R}_+ \) and \( \mathbb{R}_- \) infinitely many times, the time of the first visit to one of the half-spaces is of infinite expectation. This is a well-known fact for the simple symmetric random walk on \( \mathbb{Z} \) (easy exercise!).

**Proof.** Let us suppose that \((S)\) drifts towards \( +\infty \). Then clearly \((S)\) has a positive probability to stay positive for all positive times and so \( T^\leq \) (as well as \( T^\geq \)) has a positive probability to be infinite. It follows from (4.1) (and its extension a few line below) that \( \mathbb{E}[T_1^\geq] \) and \( \mathbb{E}[T_1^\leq] \) are finite. The case when \((S)\) drifts towards \(-\infty\) is symmetric. When \((S)\) oscillates then the ladder epoch are always finite and so their expectations are \( \infty \) by (4.1).

**Exercise 4.2.** Let \((S)\) be a one-dimensional random walk of i.i.d. increments \( X_i \). Suppose that \( H_1^\geq, H_1^\leq \) are both finite and of finite expectation. Show that \( \mathbb{E}[|X_1|] < \infty \) and \( \mathbb{E}[X] = 0. \)
Exercise 4.3. Show directly (without duality) that $\mathbb{E}[T_1^\triangleright] \leq 1$ is finite if and only if $\mathbb{E}[T_1^\triangleright] \leq 1$ is finite.

Remark 4.2. Combining the last corollary with Wald’s equality (Theorem 3.6), we deduce that for a random walk with finite mean and positive drift then we have

$$\mathbb{E}[H_1^\triangleright] = \mathbb{E}[T_1^\triangleright] \cdot \mathbb{E}[X_1].$$

4.2 Cyclic lemma and Wiener–Hopf

In this section we prove the main formula of this chapter (Theorem 4.5) which is based on a particularly elegant combinatorial lemma due to Feller\(^1\).

4.2.1 Feller’s cyclic lemma

Let $x_1, x_2, \ldots, x_n$ be real numbers which we consider as the increments of the walk $(s)$ defined by

$$s_0 = 0, s_1 = x_1, s_2 = x_1 + x_2, \ldots, s_n = x_1 + \cdots + x_n.$$ 

Recall that $i$ is a strict ascending ladder epoch for $(s)$ if $s_i > s_{i-1}, s_i > s_{i-2}, \ldots, s_i > s_0$. If $\ell \in \{0, 1, 2, \ldots, n-1\}$ we consider $(s^{(\ell)})$ the $\ell$-th cyclic shift of the walk obtained by cyclically shifting its increments $\ell$ times, that is

$$s_0^{(\ell)} = 0, s_1^{(\ell)} = x_{\ell+1}, \ldots, s_n^{(\ell)} = x_{\ell+1} + \cdots + x_n, \ldots, s_n^{(\ell)} = x_{\ell+1} + \cdots + x_1 + \cdots + x_{\ell}.$$ 

Lemma 4.3 (Feller). Suppose that $s_n > 0$. We denote by $k \in \{0, 1, 2, \ldots, n\}$ the number of cyclic shifts $(s^{(\ell)})$ with $\ell \in \{0, 1, 2, \ldots, n-1\}$ for which $n$ is a strict increasing ladder epoch. Then $k \geq 1$ and any of those cyclic shifts has exactly $k$ strict ascending ladder epochs.

Proof. Let us first prove that $k \geq 1$. For this consider the first time $\ell \in \{1, 2, \ldots, n\}$ such that the walk $(s)$ reaches its maximum. Then clearly (make a drawing) the time $n$ is a strict ascending ladder epoch for $(s^{(\ell)})$. We can thus suppose without loss of generality that $n$ is a strict ascending ladder epoch for $(s)$. It is now clear (see Fig. 4.2 below) that the only possible cyclic shifts of the walk such that the resulting walk admits a strict ascending ladder epoch at $n$ correspond to the strict ascending ladder epochs of $(s)$. Moreover these cyclic shifts do not change the number of strict ascending ladder epochs.

Remark 4.3. Beware, Feller’s combinatorial lemma does not say that the cyclic shifts $(s^{(\ell)})$ are distinct. Indeed, in the action of $\mathbb{Z}/n\mathbb{Z}$ on $\{(s^{(\ell)} : \ell \in \{0, 1, \ldots, n-1\}\}$ by cyclic shift, the size of the orbit is equal to $n/j$ where $j|n$ is the cardinal of any stabilizer of $(s^{(\ell)})$. In our case, it is easy to see that $j$ must also divide $k$ and in this case there are only $j/k$ distinct cyclic shifts having $n$ as the $k$th strict ascending ladder time.
Figure 4.2: Illustration of Feller’s combinatorial lemma. We show a walk such that \( n \) is a strict ascending ladder epoch and the cyclic shift corresponding to the second strict ascending ladder epoch.

The above lemma also holds if we replace strict ascending ladder epoch by weak/descending ladder epoch provided that \( s_n \geq 0 \) or \( s_n \leq 0 \) or \( s_n < 0 \) depending on the case. Here is an exercise whose proof is similar to Feller’s combinatorial lemma:

**Exercise 4.4.** Let \( (S) \) be a one-dimensional random walk with diffuse step distribution. Show that for every \( n \geq 1 \) the number of points of the walk lying strictly above the segment \( (0, 0) \rightarrow (n, S_n) \) is uniformly distributed on \( \{0, 1, 2, \ldots, n - 1\} \).

**Corollary 4.4.** For every \( n \geq 1 \) and any measurable subset \( A \subset \mathbb{R}^*_+ \) we have

\[
\frac{1}{n} \mathbb{P}(S_n \in A) = \sum_{k=1}^{\infty} \frac{1}{k} \mathbb{P}(T_k > n, H_k \in A).
\]

**Proof.** Let us first re-write the last lemma in a single equation

\[
1_{s_n \in A} = \sum_{i=0}^{n-1} \sum_{k=1}^{\infty} 1_{T_k^>(s^{(i)}) = n} 1_{H_k^>(s^{(i)}) \in A}.
\]

Indeed, if the walk \( (s) \) is such that \( s_n \in A \) in particular \( s_n > 0 \) and there exists a unique \( k \) such that exactly \( k \) cyclic shifts do not annulate the indicator functions on the right-hand side. Since we divide by \( k \) the total sum is one. We take expectation when \( (S) = (S) \) is a one-dimensional random walk with i.i.d. increments, then using the fact that for all \( n \geq 0 \) we have \( (S_j^{(i)})_{0 \leq j \leq n} = (S_j)_{0 \leq j \leq n} \) in distribution we deduce the statement of the corollary.

We can rewrite the last corollary in terms of measures:

\[
1_{x>0} \mathbb{P}(S_n \in dx) = \sum_{k=1}^{\infty} \frac{1}{k} \mathbb{P}(H_k^> \in dx, T_k^> = n) 1_{x>0}.
\]

---

4.2.2 Wiener–Hopf factorization

Here is the main theorem of this chapter:

**Theorem 4.5 (Spitzer–Baxter formula ; Wiener–Hopf factorization)**

For $r \in [0, 1)$ and $\mu > 0$ we have

\[
\begin{align*}
(1 - \mathbb{E}[r^{T_1} e^{-\mu H_1^r}]) &= \exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \mathbb{E}[e^{-\mu S_n} 1_{S_n > 0}]\right), \\
(1 - \mathbb{E}[r^{T_1^c} e^{\mu H_1^c}]) &= \exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \mathbb{E}[e^{\mu S_n} 1_{S_n \leq 0}]\right).
\end{align*}
\]

**Proof.** First since $r \in [0, 1)$ and $\mu > 0$ all the quantities in the last two displays are well defined. We only prove the first display since the calculation is similar for the second one. Let us start from the right hand side and write

\[
\exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \mathbb{E}[e^{-\mu S_n} 1_{S_n > 0}]\right) = \operatorname{Cor.4.4} \exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \sum_{k=1}^{\infty} \frac{1}{k} \mathbb{E}[e^{-\mu H_k^r} 1_{T_k^r = n}]\right) \]

\[
= \exp\left(-\sum_{k=1}^{\infty} \frac{1}{k} \mathbb{E}[e^{-\mu H_k^r} r^{T_k^r}]\right) \left(\mathbb{E}[e^{-\mu H_1^r} r^{T_1^r}]\right)^k \]

\[
= 1 - \mathbb{E}[e^{-\mu H_1^r} r^{T_1^r}],
\]

where in the last line we used the equality $\sum_{k=1}^{\infty} \frac{x^k}{k} = -\log(1 - x)$ for $x \in [0, 1)$. Note that we implicitly used the fact that $r < 1$ because when $T_k^r = \infty$ we needed to say that $r^{T_k^r} = 0$. This proves Spitzer’s formula \(\square\)

**Remark 4.4 (Explanation of the terminology of Wiener–Hopf factorization).** If we write

\[
\omega_r^>(\mu) = \exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \mathbb{E}[e^{-\mu S_n} 1_{S_n > 0}]\right) \quad \text{and} \quad \omega_r^<=\mu = \exp\left(-\sum_{n=1}^{\infty} \frac{r^n}{n} \mathbb{E}[e^{-\mu S_n} 1_{S_n \leq 0}]\right),
\]

then $\omega_r^>$ is analytic on the half-space $\Re(\mu) \geq 0$ whereas $\omega_r^<$ is analytic on $\Re(\mu) \leq 0$. On the imaginary line where the two functions are well defined we have

\[
\omega_r^>(it)\omega_r^<(it) = 1 - r \mathbb{E}[e^{-itX_1}]. \tag{4.2}
\]

Hence, the characteristic function of the increment of the walk (or a slight modification thereof) has been writing as a product of two analytic functions, each defined on different half-space. The idea of writing a function on a line as a product of two functions defined on a half-space goes back to Wiener & Hopf and is often useful since we can use the tools of complex analysis for each of the factors.

---

Frank Ludvig Spitzer 1926–1992

51
Exercise 4.5. Show that for \( r \in (0, 1) \) we have
\[
\sum_{n \geq 0} \mathbb{P}(T_1^\leq > n)r^n = \exp \left( \sum_{n \geq 1} \frac{r^n}{n} \mathbb{P}(S_n > 0) \right).
\]

4.2.3 Direct applications

A first application of Theorem 4.5 (or more clearly of (4.2)) is that the law of \((T_1^\geq, H_1^\geq)\) and \((T_1^\leq, H_1^\leq)\) are sufficient to recover the law of the increment (hence of the random walk), even better: the knowledge of the law of \(H_1^\geq\) and that of \(H_1^\leq\) is sufficient to recover \(\mu\). This is not at all clear from the beginning! Actually the law of \((T_1^\geq, H_1^\geq)\) is sufficient in most cases, see Exercise 4.17. Let us give another surprising corollary of the Wiener–Hopf formula:

**Corollary 4.6.** Let \((S)\) be a one-dimensional random walk with symmetric and diffuse step distribution. Hence the law of \(T_1^\geq\) is given by
\[
\mathbb{E}[r^{T_1^\geq}] = 1 - \sqrt{1 - r}, \quad r \in [0, 1), \quad \text{or equivalently } \mathbb{P}(T_1^\geq = n) = \frac{(2n - 2)!}{2^{2n-1}n!(n-1)!}, \quad n \geq 1.
\]

**Proof.** It suffices to take the first display of Theorem 4.5 and to plug \(\mu = 0\). Since by symmetry of the increments and the lack of atoms we have \(\mathbb{P}(S_n > 0) = \mathbb{P}(S_n \geq 0) = \frac{1}{2}\) it follows that
\[
1 - \mathbb{E}[r^{T_1^\geq}] = \exp \left( - \sum_{n \geq 1} \frac{r^n}{n} \mathbb{P}(S_n > 0) \right) = \exp \left( - \sum_{n \geq 1} \frac{r^n}{n} \frac{1}{2} \right) = \exp(-1/2 \log(1 - r)) = \sqrt{1 - r}.
\]
To get the exact values of \(\mathbb{P}(T_1^\geq = n)\) it suffices to develop \(1 - \sqrt{1 - r}\) in power series and to identify the coefficients.

**Remark 4.5.** It is useful to notice the asymptotic \(\mathbb{P}(T_1^\geq = n) \sim \frac{n^{-3/2}}{2\sqrt{\pi}}\) as \(n \to \infty\).

**Corollary 4.7.** The following conditions are equivalent

(i) the random walk \((S)\) drifts towards \(-\infty\)

(ii) we have \(\sum_{n \geq 1} \frac{\mathbb{P}(S_n > 0)}{n} < \infty\)

(iii) we have \(\sum_{n \geq 1} \frac{\mathbb{P}(S_n \geq 0)}{n} < \infty\).

In this case we have
\[
\log \mathbb{E}[r^{T_1^\leq}] = \sum_{n \geq 1} \frac{\mathbb{P}(S_n > 0)}{n}.
\]

**Proof.** From Theorem 4.5 with \(\mu = 0\) we get for \(r \in [0, 1)\)
\[
1 - \mathbb{E}[r^{T_1^\leq}] = \exp \left( - \sum_{n \geq 1} \frac{r^n}{n} \mathbb{P}(S_n > 0) \right).
\]
Letting $r \uparrow 1$ the left-hand side converges towards $1 - \mathbb{E} \left[ 1_{T_1^\geq < \infty} \right] = \mathbb{P}(T_1^\geq = \infty)$ whereas the right-hand side converges towards $\exp(-\sum_{n \geq 1} \frac{\mathbb{P}(S_n > 0)}{n})$. But clearly $(S)$ drifts towards $-\infty$ if and only if $T_1^\geq$ may be infinite. In this case, recall that by (4.1) we have $\mathbb{E}[T_1^\geq] = 1/\mathbb{P}(T_1^\geq = \infty)$ which immediately implies the second claim. The equivalence with the large inequality is done similarly by considering $T_1^\geq$.

Exercise 4.6. Show that we always have $\sum_{n \geq 1} \frac{1}{n} \mathbb{P}(S_n = 0) < \infty$.

Exercise 4.7. Suppose $(S)$ is a one-dimensional random walk with integrable increments that drifts towards $-\infty$. Verify directly that $\sum_{n \geq 1} \frac{\mathbb{P}(S_n > 0)}{n} < \infty$. (Hint: use the truncated increments $X_n^* = |X| \land n$).

Exercise 4.8 (Law of large numbers enhanced). Let $(S_n)_{n \geq 0}$ be a one-dimensional random walk with i.i.d. increments $X_1, X_2, \ldots$. Show that the following propositions are equivalent:

(i) $\frac{S_n}{n} \to 0$ almost surely,

(ii) $\mathbb{E}[|X|] < \infty$ and $\mathbb{E}[X] = 0$,

(iii) for every $\varepsilon > 0$ we have $\sum_{n \geq 1} \frac{1}{n} \mathbb{P}(|S_n| > \varepsilon n) < \infty$.

4.3 Applications

4.3.1 Skip-free walks

**Definition 4.1.** Let $(S)$ be a one-dimensional random walk whose step distribution $\mu$ is supported by $\mathbb{Z}$. We say that $(S)$ is skip-free ascending (resp. descending) when $\mu(\{1, 2, 3, \ldots\}) = \mu_1$ (resp. $\mu(\ldots, -3, -2, -1\}) = \mu_{-1}$); or in words when the only positive (resp. negative) jumps of $S$ are jumps of $+1$ (resp. $-1$).

The best examples of skip-free walks are simple random walks where the step distribution is supported by $\pm 1$ (they are both skip-free ascending and descending). The nice thing with skip-free ascending walk is the fact that the $k$-th ladder height $H_k^\geq$ must be equal to $k$ when it is finite. This simple observation turns out to have many implications. First, Lemma 4.4 reduces to the well-known Kemperman’s formula

**Proposition 4.8 (Kemperman’s formula).** Let $(S)$ be a skip-free ascending walk. Then for every $n \geq 1$ and every $k \geq 1$ we have

$$\frac{1}{n} \mathbb{P}(S_n = k) = \frac{1}{k} \mathbb{P}(T_k^\geq = n).$$

---

Johannes Henricus Bernardus Kemperman 1924–2011
Let us give a first application of this formula in the case of the symmetric simple random walk whose step distribution is $\frac{1}{2}(\delta_1 + \delta_{-1})$. Since this walk is both skip-free ascending and descending we have for $n \geq 1$ (due to parity reason $T^<_1$ and $T^>_1$ have to be odd)

$$P(T^<_1 = 2n - 1) = \frac{1}{2n-1} P(S_{2n-1} = -1) = \frac{1}{2n-1} 2^{-(2n-1)} \left(\frac{2n-1}{n}\right) = 2^{-2n+1} \frac{(2n-2)!}{n!(n-1)!}. \quad (4.3)$$

We recover the probability that a symmetric continuous random walk first hits $\mathbb{R}_-$ at time $n$. Surprising isn’t it? Do you have a simple explanation of this phenomenon?

**Exercise 4.9.** Let $(S_n)_{n \geq 0}$ be a one-dimensional random walk such that $P(S_{2n+1} > 0) = \frac{1}{2}$ and $P(T^>_1 \in 2\mathbb{Z}_+) = 0$. Show that the step distribution of $(S)$ is given by $\frac{1}{2}(\delta_\alpha + \delta_{-\alpha})$ for some $\alpha > 0$.

**Exercise 4.10 (Borel distribution).** Consider $(S)$ the one-dimensional random walk with step distribution given by the law of $\mathcal{P}_1 - 1$ where $\mathcal{P}_1$ is a Poisson random variable of parameter 1. Compute the distribution of $T^<_1$ and deduce that

$$\sum_{n=1}^{\infty} \frac{n^{n-1}}{n!} e^{-n} = 1.$$

(Do you have an elementary way to deduce the last display?)

**Exercise 4.11.** Let $(S)$ be a skip-free ascending random walk started from $S_0 = 1$. Prove that

$$P_1(T^<_1 = n, S_n = 0) = \frac{1}{n} P_1(S_n = 0).$$

**Ballot theorem**

**Lemma 4.9.** Let $(S)$ be a skip-free ascending random walk. Then for every $n \geq 1$ and every $k \geq 1$ we have

$$P(S_i > 0, \forall 1 \leq i \leq n \mid S_n = k) = \frac{k}{n}.$$

**Proof.** By duality we have

$$P(S_i > 0, \forall 1 \leq i \leq n \text{ and } S_n = k) = P_{\text{duality}}(n \text{ is a strict ascending ladder epoch for } S \text{ and } S_n = k)$$

$$= P_{\text{skip free}}(T^>_k = n)$$

$$= P_{\text{Prop. 4.8}}(S_n = k).$$

Let us give an immediate application which is useful during election days:

**Theorem 4.10 (Ballot theorem)**

*During an election, candidates A and B respectively have $a > b$ votes. Suppose that votes are spread uniformly in the urn. What is the chance that during the counting of votes,
candidate A is always ahead?

answer: \( a - b \over a + b \).

**Proof.** Let us model the scenario by a uniform path making only +1 or \(-1\) steps which starts at \((0,0)\) and ends at \((a + b, a - b)\). The +1 steps correspond to votes for candidate A and the \(-1\) steps for votes for B. Hence we ask about the probability that such a path stay positive between time 1 and \(a + b\). We just remark that such a walk has the same distribution as the first \(a + b\) steps of \((S_k)_{0 \leq k \leq a+b}\) a simple random walk (with \(\pm 1\) steps with equal probability) conditioned on \(S_{a+b} = a - b\): indeed each \(\pm\) path starting at \((0,0)\) and ending at \((a + b, a - b)\) has the same probability under that distribution. The conclusion follows from Lemma 4.9. \(\square\)

### Staying positive

If \((S)\) is a one-dimensional random walk with integrable increments with positive mean then by the law of large numbers, the probability that the walk stays positive after time 1 is strictly positive. We compute below this probability in the case of skip-free ascending and skip-free descending walks:

**Corollary 4.11.** If \((S)\) is skip-free ascending such that \(\mathbb{E}[S_1] > 0\) then we have

\[
\mathbb{P}(S_i > 0 : \forall i \geq 1) = \mathbb{E}[S_1].
\]

**Proof.** We have

\[
\mathbb{P}(S_i > 0 : \forall i \geq 1) = \lim_{n \to \infty} \mathbb{P}(S_i > 0 : \forall 1 \leq i \leq n) = \lim_{n \to \infty} \mathbb{E}[\mathbb{P}(S_i > 0 : \forall 1 \leq i \leq n \mid S_n)] = \lim_{n \to \infty} \mathbb{E}\left[\frac{S_n}{n} \mathbf{1}_{S_n > 0}\right] \to \mathbb{E}[S_1],
\]

by the strong law of large numbers (since \(S_n/n \to \mathbb{E}[S_1]\) almost surely and in \(L^1\)). \(\square\)

**Proposition 4.12.** If \((S)\) is skip-free descending (with \(\mu \neq \delta_0\)) then \(\mathbb{P}(S_n \geq 0, \forall n \geq 0) = 1 - \alpha\) where \(\alpha\) is the smallest solution in \(\alpha \in [0, 1]\) to the equation:

\[
\alpha = \sum_{k=-1}^{\infty} \mu_k \alpha^{k+1}. \tag{4.4}
\]

**Proof.** Since \(\mu\) is supported by \(\{-1, 0, 1, \ldots\}\) its mean \(m\) is well-defined and belongs to \([-1, \infty]\). We already know from the previous chapter that \(\mathbb{P}(S_n \geq 0, \forall n \geq 0) > 0\) if and only if \(m > 0\) (we use here the fact that the walk is not constant since \(\mu \neq \delta_0\)). We denote by \(\tau_{<0}\) the hitting time of \(\{\ldots, -3, -2, -1\}\) by the walk \((S)\). Notice that by our assumptions if \(\tau_{<0}\) is finite then necessarily \(S_{\tau_{<0}} = -1\). To get the equation of the proposition we perform one step of the random walk \(S\): if \(S_1 = -1\) then \(\tau_{<0} < \infty\). Otherwise if \(S_1 \geq 0\) then consider the stopping times

\[
\theta_0 = 0, \quad \theta_1 = \inf\{k \geq 1 : S_k = S_1 - 1\}, \quad \theta_2 = \inf\{k \geq \theta_1 : S_k = S_1 - 2\}, \ldots
\]

55
By the strong Markov property we see that \((\theta_{i+1} - \theta_i)_{i \geq 0}\) are i.i.d. of law \(\tau < 0\). Furthermore on the event \(S_1 \geq 0\) we have

\[
\{\tau < \infty\} = \bigcap_{n=0}^{S_1-1} \{\theta_{n+1} - \theta_n < \infty\}.
\]

Taking expectation, we deduce that \(\mathbb{P}(\tau < \infty)\) is indeed solution to (4.4). Now, notice that \(F : \alpha \mapsto \sum_{k=-1}^{\infty} \mu_k \alpha^{k+1}\) is a convex function on \([0, 1]\) which always admits 1 as a fixed point. Since \(F'(1) = m + 1\) we deduce that \(F\) admits two fixed points in the case \(m > 0\). But when \(m > 0\) we already know that \(\alpha < 1\) and so \(\alpha\) must be equal to the smallest solution of (4.4).

Exercise 4.12. Let \((S)\) be a skip-free descending random walk which drifts towards \(+\infty\). Compute the law of \(\inf\{S_k : k \geq 0\}\).

4.3.2 Arcsine law

They are many different arcsine laws in the theory of random walk. We restrict to the usual one in the simplest case only to illustrate another application of our preceding results.

**Proposition 4.13** (1st Arcsine law). Let \((S)\) be a one-dimensional random walk with a symmetric step distribution without atoms. We put \(K_n = \inf\{0 \leq k \leq n : S_k = \sup_{0 \leq i \leq n} S_i\}\) then

\[
\frac{K_n}{n} \xrightarrow{n \to \infty} \frac{dx}{\pi \sqrt{x(1-x)}} 1_{x \in (0,1)}.
\]

The name arcsine comes from the cumulative distribution function of the right-hand side which is \(\frac{2}{\pi} \arcsin(\sqrt{x})\).

![The arcsine distribution](image)

**Figure 4.3:** The arcsine distribution

**Remark** 4.6. Quoting Feller “Contrary to intuition, the maximum accumulated gain is much more likely to occur towards the very beginning or the very end of a coin-tossing game than somewhere in the middle.”
Proof. Using duality we can compute exactly

$$
\mathbb{P}(K_n = k) = \mathbb{P}(T_1^\geq n-k)\mathbb{P}(T_1^\geq k) \sim \frac{1}{\pi \sqrt{k(n-k)}}.
$$

where the last asymptotic holds uniformly in $k \gg 1$ and $n-k \gg 1$. If we add a little blur to $K_n$ and consider $\tilde{K}_n = K_n + U_n$ where $U_n$ is independent of $K_n$ and uniformly distributed over $[0, 1]$. Then clearly $\tilde{K}_n/n$ has a density with respect to Lebesgue measure which converges pointwise towards the density of the arcsine law. It follows from Scheffé’s lemma that $\tilde{K}_n/n$ converges in total variance towards the arcsine law and consequently $K_n/n$ converges in distribution towards the arcsine law since $U_n/n \to 0$ in probability.

Exercise 4.13 (Scheffé’s lemma). Let $X_n, X$ be random variables having densities $f_n, f$ with respect to a background measure $\pi$. We suppose that $f_n \to f$ pointwise $\pi$-almost everywhere. Prove that

(i) $f_n \to f$ in $L^1(\pi)$.

(ii) $d_{TV}(f_n d\nu, f d\nu) \to 0$ where $d_{TV}$ is the total variation distance,

(iii) in particular deduce that $X_n \to X$ in distribution.

More exercises.

Exercise 4.15 (Another approach to Wiener–Hopf factorization, see [15] and [5]). Let $(S_n)_{n \geq 0}$ be a one-dimensional oscillating random walk. On the event $T_1^\leq \geq 2$, we put $Y = \inf\{S_i : 1 \leq i \leq T_1^\leq -1\}$ and define the random instant $\theta = \sup\{i \leq T_1^\leq : S_\theta = Y\}$. We put $\overleftarrow{S}$ and $\overrightarrow{S}$ for the processes defined by

$$
\overleftarrow{S}_i = S_\theta - S_{\theta - i}, \quad \text{for } 0 \leq i \leq \theta,
$$

$$
\overrightarrow{S}_i = S_{\theta + i} - S_\theta, \quad \text{for } 0 \leq i \leq T_1^\leq - \theta.
$$

Otherwise if $T_1^\leq = 1$ we put $\overleftarrow{S} = \overrightarrow{S} = \dagger$ a cemetery point.
1. Let \((S'_i)_{0 \leq i \leq \tau'}\) and \((S''_i)_{0 \leq i \leq \tau''}\) two independent random walks of law \(S\) stopped respectively at \(T^\geq_1\) and \(T^<_1\). Show that for any function \(\phi\) so that \(\phi(\hat{\tau}, \hat{\tau}) = 0\) we have
\[
E\left[\phi(\overrightarrow{S}, \overleftarrow{S})\right] = E\left[\phi(S', S'')1_{S'_{\tau'}^< + S''_{\tau''}^< < 0}\right],
\]
and in particular that for any \(t \in \mathbb{R}\) we have
\[
E[e^{-itH^<_1}] - E[e^{-itH^<_1}e^{itH^>_1}1_{H^<_1 < H^>_1}] = E[e^{itX}1_{X \leq 0}],
\]
where \(X\) is a step of the random walk and \(H^<_1 = S_{T^<_1}\) and \(H^>_1\) are two independent versions of its increasing and decreasing ladder heights.

2. By adapting the argument with \(T^<_1\) recover the Wiener–Hopf factorization:
\[
\left(1 - E[e^{-itH^<_1}]\right)\left(1 - E[e^{itH^>_1}]\right) = 1 - E[e^{itX}].
\]

**Exercise 4.16 (Renewal function).** Let \((S)\) be a one-dimensional random walk with a non trivial aperiodic step distribution on \(\mathbb{Z}\). We recall that \((T^<_i, H^<_i)_{i \geq 0}\) are respectively the strict descending ladder times and heights, and \((T^>_i, H^>_i)_{i \geq 0}\) are the weak ascending ladder times and heights.

We introduce the **renewal function** for \(x \geq 0\)
\[
V(x) = \sum_{k=0}^{\infty} P(-x \leq H^<_k \leq 0) = \sum_{n=0}^{\infty} P(n \text{ is a strict descending ladder time and } S_n \in [-x, 0]),
\]
and we put \(V(x) = 0\) when \(x < 0\).

1. Show that \(V(x)\) is finite for any \(x \geq 0\).

2. Using duality, show that we have
\[
V(x) = E\left[\sum_{j=0}^{T^<_1-1} 1_{S_j \geq -x}\right].
\]
3. (a) Show that $V$ is bounded if and only if $(S)$ drifts towards $+\infty$.
   (b) We suppose that $(S)$ drifts towards $-\infty$ and that $\mathbb{E}[|S_1|] < \infty$. Give an asymptotic for $V(x)$ as $x \to \infty$.

4. We suppose in this question that $(S)$ oscillates or drifts towards $+\infty$. The goal is to prove that $V$ is a harmonic function for the walk $(S)$ killed upon reaching $\mathbb{Z}_{<0} = \{\ldots, -2, -1\}$, i.e. for any $x \geq 0$ and any $n \geq 0$ we have
   \[ V(x) = \mathbb{E}_x[V(S_n)1_{\tau>n}], \]
   where under $\mathbb{E}_x$ the walk starts from $x \geq 0$ and $\tau = \inf\{k \geq 0 : S_k \in \mathbb{Z}_{<0}\}$.
   (a) Show that it suffices to prove the case $n = 1$.
   (b) Using duality prove the case $n = 1$ and $x = 0$.
   (c) By writing $V(x) = \mathbb{E}[\mathcal{N}_{-x,0}]$ where $\mathcal{N}_A$ is the number of strict descending heights falling in $A$, deduce the general case.
   (d) Deduce that in the case when $(S)$ drifts towards $+\infty$ we have the explicit form:
   \[ V(x) = \frac{\mathbb{P}_x(\tau = \infty)}{\mathbb{P}_0(\tau = 0)}. \]

Exercise 4.17 (From [7]). Let $(S_n)_{n \geq 0}$ be a one-dimensional random walk with iid increments of law $\mu$ not supported by $\mathbb{R}_-$ and with compact support. For $t \in \mathbb{R}$ we write
   \[ \phi(t) = \int_{\mathbb{R}} d\mu(x) e^{tx} \]
   which is well-defined and analytic on $\mathbb{R}$ in our case. The goal is to prove that $\mu$ is characterized by the law of $(H^>, T^>)$ the ascending space-time first ladder variables.
   1. Show that the law of $(H^>, T^>)$ give access to $\mathbb{P}(S_n > 0)$ and to $\mu^{*n}$ restricted to $\mathbb{R}^*_+$.
   2. Deduce that the law of $(H^>, T^>)$ enables us to decide oscillation, drift, recurrence or transience of $(S)$.
   3. In this question we suppose that $\mu$ has positive mean.
      (a) Using large deviations, show that there exists $\alpha > 0$ such that for $n \geq 1$ we have
      \[ \mathbb{P}(S_n \leq 0) \leq e^{-\alpha n}. \]
      (b) Show that for $t > 0$ small enough we have
      \[ \lim_{n \to \infty} \left( \mathbb{E}[e^{tS_n}1_{S_n>0}] \right)^{1/n} = \phi(t). \]
      (c) Deduce that the law of $(H^>, T^>)$ characterizes $\mu$. 

59
4. Back to the general case where $\mu$ has compact support.

(a) Show that there exists $\lambda > 0$ with $\phi(\lambda) < \infty$ and $\phi'(\lambda) > 0$.

(b) By considering $\mu_\lambda(dx) = \frac{\lambda^x}{\phi(\lambda)} \mu(dx)$ and the associated random walk $(S^{(\lambda)}_n)$ show that

$$\mathbb{P}(S^{(\lambda)}_n > 0) = \frac{\mathbb{E}[e^{\lambda S_n} 1_{S_n > 0}]}{(\phi(\lambda))^n}.$$ 

(c) Prove that $(S^{(\lambda)}_n)$ drift towards $+\infty$ and conclude.
Chapter V: Renewal theory (Exercices de style)

Disclaimer: As usual in these notes and even more in this section, the main goal is rather to present a couple of ideas and techniques which are common in probability theory (generating function method, coupling, recursive distributional equations, harmonic functions...) rather than the shortest proof to well-known and useful results (see e.g. [13]). In particular, we will present 4 different proofs of Theorem 5.1 (in its simplest version).

In this chapter we study the behavior of a one-dimensional random walk \((S)\) with step distribution \(\mu\) supported by \(\mathbb{R}_+\) and whose mean we denote by \(m \in [0, \infty]\). Unless in the trivial case \(\mu = \delta_0\) the walk drifts to \(\infty\) and our goal is this chapter is to understand the asymptotic density of the random set

\[ R = \{S_0, S_1, \ldots, S_n, \ldots\}. \]

Such a process is often used to model the breakdown of different machines, then the random times \(X_i\) represent the time between one machine breaking down before another one does. The random set \(R\) then correspond to the times when a machine needs to be replaced. We first suppose that that \(\mu\) is supported by \(\{1, 2, \cdots\}\) and that \(\text{gcd} \text{(supp}(\mu)) = 1\). Hence \(R\) is a random set of points of \(\mathbb{Z}_+\) so that \(\mathbb{P}(n \in R)\) is positive for \(n\) large enough. The main result of this chapter is the following:

**Theorem 5.1 (Erdős–Feller–Pollard)**

Under the above hypotheses we have

\[ \lim_{n \to \infty} \mathbb{P}(n \in R) = \frac{1}{m}. \]

Notice that even if \(m = \int \mu(dx)x = \infty\) the above statement has a well-defined meaning. Remark also that by the strong law of large numbers we have \(n^{-1}S_n \to m\) almost surely as \(n \to \infty\). It follows that \(N_n = \sup\{k \geq 0 : S_k \leq n\}\) satisfies \(n^{-1}N_n \to \frac{1}{m}\) almost surely. This easily implies a weaker “integrated” version of the last result:

\[ \frac{1}{n} \sum_{i=0}^{n} \mathbb{P}(i \in R) = \frac{1}{n} \mathbb{E}[\#(R \cap [0, n])] = \frac{1}{n} \mathbb{E}[N_n] \xrightarrow{n \to \infty} \frac{1}{m}, \]

where in the last convergence we used dominated convergence.
5.1 Proof via analytic combinatorics

In this section we give a proof of Theorem 5.1 when \( m < \infty \) using analytical method based on generating series. We start with the case when \( \mu \) has bounded support as a training.

5.1.1 Bounded support

We suppose here that \( \mu \) is supported by \( \{1, 2, \ldots, n_0\} \) for some \( n_0 \geq 1 \). Hence \( \mu \) can be encoded by the polynomial

\[
P(z) = z\mu_1 + z^2\mu_2 + \cdots + z^{n_0}\mu_{n_0} \in \mathbb{R}[X].
\]

Clearly the generating function of the law of \( S_k = X_1 + \cdots + X_k \) is given by \( (P(z))^k \). Summing-up for all \( k \geq 0 \) we deduce the following equality of formal series

\[
\frac{1}{1 - P(z)} = \sum_{k \geq 0} (P(z))^k
= \sum_{k \geq 0} \sum_{n \geq 0} z^n \Pr(S_k = n)
= \sum_{n \geq 0} \mathbb{E}[\#\{k \geq 0 : S_k = n\}] z^n
= \sum_{n \geq 0} \Pr(n \in \mathbb{R}) z^n,
\]

where we have used the fact that \( X \geq 1 \) to argue that if \( n \) is visited by the walk \( S \), then it is visited once. The last equality actuality makes perfect sense for all \( z \in \mathbb{C} \) such that \( |z| < 1 \). We know use partial fraction decomposition on \( (1 - P(z))^{-1} \):

- Notice first that \( z = 1 \) is a trivial pole of this function. It is of order 1 since \( P'(1) = m > 0 \).

- All the zeros of \( 1 - P(.) \) must have modulus larger than 1 since otherwise

  \[
  |z\mu_1 + z^2\mu_2 + \cdots + z^{n_0}\mu_{n_0}| \leq |z|\mu_1 + |z|^2\mu_2 + \cdots + |z|^{n_0}\mu_{n_0} < 1
\]

  (this can also directly be see from (5.1) since the equality makes sense for all \( |z| < 1 \)).

- We also claim that the aperiodicity condition on \( \mu \) ensures that \( z = 1 \) is the only root of \( 1 - P \) on \( S^1 \). Indeed, if \( z = e^{i\theta} \) with \( \theta \in (0, 2\pi) \) was another root of \( 1 - P \), by the equality case of the triangle inequality it would follow that \( \mu_k z^k = \mu_k e^{ik\theta} \) must be real and positive and in fact the same is true for each \( k \in \bigcup_{i \geq 1} \text{Supp}(\mu^{*i}) \). Since \( \text{gcd}(\text{Supp}(\mu)) = 1 \) we can find two consecutive such \( k \) in \( \bigcup_{i \geq 1} \text{Supp}(\mu^{*i}) \) and so \( \theta = 0 \mod 2\pi \) which is a contradiction.

Hence the partial fraction decomposition of \( 1/(1 - P) \) reads as follows

\[
\frac{1}{1 - P(z)} = (P'(1))^{-1} \frac{1}{z - 1} + \sum_i \frac{\alpha_i}{(z - \beta_i)^{\ell_i}},
\]

62
where \( \ell_i \geq 1, \alpha_i \in \mathbb{C} \) and \( \beta_i \) are the other roots of \( 1 - P \) in particular \( |\beta_i| > 1 \). If we now expand each of these terms in series, we see that the expansion of the first term gives \( \frac{1}{m} \sum_{n \geq 0} z^n \) whereas the expansion of the other terms contribute with a series of the form

\[
\sum_{n \geq 0} z^n \zeta_{n,i},
\]

where \( \zeta_{n,i} = o(1) \) as \( n \to \infty \) (more precisely \( |\zeta_{n,i}| = O(|\beta_i|^{-n \ell_i}) \)). Taking the coefficient in front of \( z^n \) in both sides of (5.1) we indeed deduce the desired result i.e.

\[
[z^n] \frac{1}{1 - P(z)} = \mathbb{P}(n \in \mathcal{R}) = \frac{1}{m} + o(1).
\]

### 5.1.2 Unbounded support with \( m < \infty \)

We now suppose that \( \mu \) has a possibly unbounded support on \( \{1, 2, \ldots\} \) but that \( m = \sum_{k \geq 0} k \mu_k < \infty \). Our surrogate to the explicit partial fraction decomposition will be a theorem of Wiener on power series:

**Lemma 5.2** (Wiener). If \( g(z) = \sum_{n \geq 0} a_n z^n \) is a power series with \( \sum_{n \geq 0} |a_n| < \infty \) which has no zeros inside \( \mathbb{D} \) then \( 1/g(z) \) has a power series expansion

\[
\frac{1}{g(z)} = \sum_{n \geq 0} b_n z^n \quad \text{with} \quad \sum_{n \geq 0} |b_n| < \infty.
\]

**Proof.** See [?, Theorem 18.21].

Following the last section, if \( P(z) = \sum_{k \geq 1} z^k \mu_k \) is the generating function of \( \mu \) (which is not necessarily a polynomial function) then

\[
\frac{1 - z}{1 - P(z)} = (1 - z) \sum_{n \geq 0} z^n \mathbb{P}(n \in \mathcal{R}) = \sum_{n \geq 0} z^n (\mathbb{P}(n \in \mathcal{R}) - \mathbb{P}(n - 1 \in \mathcal{R})).
\]

It is easy then to check that \( \frac{1 - P(z)}{1 - z} = \sum_{n \geq 0} z^n \sum_{k=n+1}^{\infty} \mu_k \) and so this function satisfies the requirements of the lemma because

\[
\sum_{n \geq 0} \sum_{k \geq n+1} \mu_k = m < \infty.
\]

Applying the above lemma we deduce that \( \sum |\mathbb{P}(n \in \mathcal{R}) - \mathbb{P}(n - 1 \in \mathcal{R})| < \infty \) and consequently by Abel’s theorem that \( \mathbb{P}(n \in \mathcal{R}) \) converges as \( n \to \infty \) towards

\[
\lim_{n \to \infty} \mathbb{P}(n \in \mathcal{R}) = \lim_{z \to 1} \frac{1 - z}{1 - P(z)} = \frac{1}{P'(1)} = \frac{1}{m}.
\]

**Remark 5.1.** In passing we have proved a slightly stronger version of Theorem 5.1 since when \( m < \infty \) we have

\[
\sum_{n \geq 0} |\mathbb{P}(n \in \mathcal{R}) - \mathbb{P}(n + 1 \in \mathcal{R})| < \infty.
\]
5.2 Finite mean case via stationarity and coupling

The probabilistic reader may be disappointed by the last proofs based on analytical methods. In this section, we provide an alternative proof of Theorem 5.1 in the case when $m < \infty$ based on the probabilistic concepts of coupling and stationarity.

5.2.1 Point processes and stationarity

Definition 5.1. A renewal set $S$ is a set of points $\{s_0 < s_1 < \ldots\}$ in $\mathbb{Z}_+$. Such a set is naturally associated with its inter-times $x_0 = s_0 - 0, x_1 = s_1 - s_0, x_2 = s_2 - s_1$ etc. We can define a translation operation $\theta$ on the set of all renewal sets by setting $\theta S = S'$ where $S'$ is described by its inter-times $(x'_i)_{i \geq 0}$ where

$$
\begin{align*}
\text{if } x_0 = 0 \text{ then } & \begin{cases} 
x'_0 = x_1 - 1 \\
x'_i = x_{i+1} \text{ for } i \geq 1
\end{cases} \\
\text{otherwise if } x_0 > 0 \text{ then } & \begin{cases} 
x'_0 = x_0 - 1 \\
x'_i = x_i \text{ for } i \geq 1
\end{cases}
\end{align*}
$$

Figure 5.1: Illustration of the definition of a renewal set and its translate.

In words, $\theta S$ is just obtained by erasing the first point 0 of $\mathbb{Z}_+$ (and possibly the point of $S$ at this position) and translating all other values and points by 1. Our strategy to prove Theorem 5.1 is to show the following stronger convergence

$$
\theta^n R \xrightarrow{d} \tilde{R},
$$

where $\tilde{R}$ is a renewal set whose law will be described later on and satisfies $\mathbb{P}(0 \in \tilde{R}) = \frac{1}{m}$ (recall that we focused first on the case $m < \infty$). The convergence in distribution of renewal set in the last display simply means finite-dimensional convergence of its associated inter-times. If (5.2) is granted, we then have in particular

$$
\mathbb{P}(n \in R) = \mathbb{P}(0 \in \theta^n R) \xrightarrow{n \to \infty} \mathbb{P}(0 \in \tilde{R}) = \frac{1}{m},
$$

as desired.

A stationary renewal set

We first describe explicitly the law of $\theta^n R$.

Proposition 5.3. The law of the renewal set $\theta^n R$ is described by its inter-times $(X_i^{(n)})_{i \geq 0}$ whose law is characterized as follows:
\( (X_i^{(n)})_{i \geq 1} \) are i.i.d. random variables of law \( \mu \) independent of \( X_0^{(n)} \),

- the law of \( X_0^{(n)} \) is prescribed by the following recursive distributional equation: \( X_0^{(0)} = 0 \) almost surely and for \( n \geq 1 \) we have

\[
X_0^{(n+1)} \equiv (X_0^{(n)} - 1)1_{X_0^{(n)}>0} + (X - 1)1_{X_0^{(n)}=0},
\]

where \( X \) is of law \( \mu \) and independent of \( X_0^{(n)} \).

**Proof.** This is merely a writing exercise. The case \( n = 1 \) is granted by definition of the renewal set \( R \). Consider now \( f_0, f_1, f_2, \ldots, f_k \) bounded measurable functions. Then by definition of \( \theta \) we have

\[
\mathbb{E}\left[ \prod_{i=0}^{k} f_i(X_i^{(n+1)}) \right] = \mathbb{E}\left[ 1_{X_0^{(n)}>0}f_0(X_0^{(n)} - 1) \prod_{i=1}^{k} f_i(X_i^{(n)}) \right] + \mathbb{E}\left[ 1_{X_0^{(n)}=0}f_0(X_1^{(n)} - 1) \prod_{i=1}^{k} f_i(X_i^{(n)}) \right]
\]

\[= \text{ind. hyp} \mathbb{E}[1_{X_0^{(n)}>0}f_0(X_0^{(n)} - 1)] \prod_{i=1}^{k} \mathbb{E}[f_i(X)] + \mathbb{E}[1_{X_0^{(n)}=0}f_0(X_1^{(n)} - 1)] \prod_{i=1}^{k} \mathbb{E}[f_i(X)].
\]

This exactly tells us that \( (X_i^{(n+1)})_{i \geq 0} \) has the desired law. \( \square \)

Equation (5.3) is an example of a recursive distributional equation. Indeed, if \( \mu_n \) is the law of \( X_0^{(n)} \) then this equation states that

\[
\mu_{n+1} = \phi(\mu_n),
\]

where the function \( \phi \) maps a law \( \nu \) supported by \( \mathbb{Z}_+ \) to the law \( \phi(\nu) \) of \( (Y - 1)1_{Y>0} + (X - 1)1_{Y=0} \) where \( Y \) has law \( \nu \) and is independent of \( X \) which has law \( \mu \). If we interpret the last display as a classical iteration scheme (but in the space of measures) we are naturally yield to consider fixed point (and contraction property) for the mapping \( \phi \). This is simple in our case:

**Lemma 5.4.** Suppose \( m < \infty \) then Equation (5.4) has a unique fixed point \( \nu \) whose law is given by

\[
\nu_k = \frac{1}{m} \mu((k, \infty)), \quad \text{for} \quad k \geq 0.
\]

**Proof.** We can rewrite the equation \( \nu = \phi(\nu) \) equivalently as

\[
\nu_k = \nu_{k+1} + \nu_0 \mu_{k+1}, \quad \text{for} \quad k \geq 0.
\]

Summing these equation for \( k = n, n+1, \ldots \) we find that \( \nu_k = \nu_0 \mu((k, \infty)) \) for all \( k \geq 0 \). Since \( \nu \) has to be a probability this forces \( \nu_0 \) to be the inverse of \( \sum_{k \geq 0} \mu((k, \infty)) = m \). In this case the last calculation is reversible and this proves the lemma. \( \square \)
Remark 5.2. One can interpret the law \( \nu \) of the last lemma from a probabilistic point of view: Let \( \mu \) denote the size biased distribution of \( \mu \) given by

\[
\mu_k = \frac{k \mu_k}{m} \quad \text{for } k \geq 1.
\]

If we first sample \( Z \) according to \( \mu \) and next conditionally on \( Z \) sample \( Y \in \{0, 1, 2, \ldots, Z\} \) uniformly at random then the law of \( Y \) follows \( \nu \). This has the following interpretation: when \( n \) is very large the point \( n \) lies in an interval between two points of the renewal set whose law is that of \( X_1 \) biased by its length. Furthermore, conditionally on the length of this interval, the point \( n \) is asymptotically uniformly distributed in it.

**Definition 5.2.** Suppose that the mean \( m \) of \( \mu \) is finite. Then we let \( \tilde{R} \) be the renewal set whose inter-times are independent and given by \( X_0 \sim \nu \) and \( X_i \sim \mu \) for \( i \geq 1 \).

**Proposition 5.5.** The renewal set \( \tilde{R} \) is stationary in the sense that \( \theta \tilde{R} = \tilde{R} \) in distribution.

**Proof.** This is a consequence of the proof of Proposition 5.3 as well as the fact that \( \nu \) is a fixed point for Equation (5.4).

One way to finish the proof of Theorem 5.1 (more precisely (5.2)) would be to use Proposition 5.3 and doing the following exercise:

**Exercise 5.1.** (Contraction for the recursive distributional equation (5.4)). If \( \nu_0 \) is an arbitrary law on \( \mathbb{Z}_+ \), define the sequence of probability measures \( (\nu_n)_{n \geq 0} \) recursively by \( \nu_{n+1} = \phi(\nu_n) \) as in (5.4) for \( n \geq 0 \).

1. Show that if \( \int \mu(dx)x < \infty \) then \( \nu_n \to \nu \) weakly (\( \nu \) defined in Proposition 5.4).

2. Otherwise show that if \( m = \infty \) then for all \( k \geq 0 \) we have \( \nu_n(k) \to 0 \) as \( n \to \infty \).

**Exercise 5.2.** Adapt the last section in the case when we define a renewal set to be a two-sided set of points \( \{ \ldots < s_{-2} < s_{-1} < s_0 < s_1 < s_2 < \ldots \} \) of \( \mathbb{Z} \). The translation \( \theta \) consists then in moving the underlying points of \( \mathbb{Z} \) by +1.

5.2.2 Coupling argument

If we were working with the stationary renewal set \( \tilde{R} \) instead of \( R \) then the proof of Theorem 5.1 would be a piece of cake since for \( n \geq 0 \) we have

\[
\mathbb{P}(n \in \tilde{R}) = \mathbb{P}(0 \in \theta^n \tilde{R}) = \mathbb{P}(0 \in \tilde{R}) = \nu_0 = \frac{1}{m}.
\]

Equation (5.2) is to couple \( R \) and \( \tilde{R} \) (i.e. to construct both of them on the same probability space) in such a way that for \( n \) large enough (this large enough being random) we have \( \theta^n \tilde{R} = \theta^n R \). Let us proceed. We start with \( (Y_i)_{i \geq 0} \) and \( (Y'_i)_{i \geq 0} \) be independent variables
so that $Y_0 = 0$ almost surely, $Y'_0 \sim \nu$ and for $i \geq 1$ we have $Y_i \sim Y'_i \sim \mu$. We associate with these variables the random walk 
\[ \Delta_n = (Y_0 + \cdots + Y_n) - (Y'_0 + \cdots + Y'_n). \]
Hence $(\Delta)$ is a centered random walk and so is recurrent by Theorem 3.5. We denote $\tau = \text{inf}\{k \geq 0 : \Delta_k = 0\}$. We then construct two renewal sets $S$ and $\tilde{S}$ whose inter-times $(X_i)$ and $(\tilde{X}_i)$ are described as follows:

- for $0 \leq i \leq \tau$ we put $X_i = Y_i$ and $\tilde{X}_i = Y'_i$,
- whereas for $i \geq \tau + 1$ we put $X_i = \tilde{X}_i = Y_i$.

**Proposition 5.6.** The above construction $(S, \tilde{S})$ is indeed a coupling of $\mathcal{R}$ and $\tilde{\mathcal{R}}$, in other words we do have $\mathcal{R} = S$ and $\tilde{\mathcal{R}} = \tilde{S}$ in law.

**Proof.** It is clear that $\mathcal{R} = S$ in distribution since the inter-times of $\mathcal{R}$ are given by the $X_i$ no matter $\tau$. In the case of $\tilde{\mathcal{R}}$ we have to show that $(\tilde{X}_i)_{i \geq 0}$ are i.i.d. random variables of law $\nu$ for $i = 0$ and $\mu$ for $i \geq 1$. Let $f_0, \ldots, f_k$ be bounded measurable functions and let us compute

\[ \mathbb{E}\left[ \prod_{i=0}^{k} f_i(\tilde{X}_i) \right] = \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau<k} f_k(Y_k) \right] + \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau \geq k} f_k(Y'_k) \right]. \]

Noticing that $\{\tau \geq k\}$ is measurable with respect to $Y_0, \ldots, Y_{k-1}, Y'_0, \ldots, Y'_{k-1}$ we get by independence that

\[ \mathbb{E}\left[ \prod_{i=0}^{k} f_i(\tilde{X}_i) \right] = \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau<k} \right] \mathbb{E}[f_k(Y_k)] + \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau \geq k} \right] \mathbb{E}[f_k(Y'_k)] \]

\[ = \left( \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau<k} \right] + \mathbb{E}\left[ \prod_{i=0}^{k-1} f_i(\tilde{X}_i) \mathbf{1}_{\tau \geq k} \right] \right) \cdot \mathbb{E}[f_k(Y_1)]. \]

Iterating the argument until we reach $k = 0$ we have proved the proposition. □

**Proof of Eq. (5.2).** We consider the last coupling $(S, \tilde{S})$ of $\mathcal{R}$ and $\tilde{\mathcal{R}}$. If $f$ is a bounded measurable function we can write

\[ \mathbb{E}[f(\theta^n \mathcal{R})] = \mathbb{E}[f(\theta^n S)] \]

\[ = \mathbb{E}[f(\theta^n S) \mathbf{1}_{\tau \geq n}] + \mathbb{E}[f(\theta^n \tilde{S}) \mathbf{1}_{\tau < n}] \]

\[ = \mathbb{E}[f(\theta^n S) \mathbf{1}_{\tau \geq n}] - \mathbb{E}[f(\theta^n \tilde{S}) \mathbf{1}_{\tau \geq n}] + \mathbb{E}[f(\theta^n \tilde{S})]. \]

Since $f$ is bounded and because $\mathbb{P}(\tau \geq n) \to 0$ the first two terms in the last display tend to 0 as $n \to \infty$. As for the third term, arguing as in (5.5) we see that it is equal to $\mathbb{E}[f(\tilde{S})]$ no matter the value of $n$. Hence the whole thing tends to $\mathbb{E}[f(\tilde{S})]$ as wanted. □
5.3 A deceptively simple (but tricky) proof in the general case

In this section we finally give an elementary proof of Theorem 5.1 which is also valid in the case \( m = \infty \). To simplify notation we write

\[
u_n = \mathbb{P}(n \in \mathbb{R}) \quad \text{for } n \geq 0,
\]

with \( \nu_0 = 1 \) and \( \nu_n = 0 \) for \( n < 0 \). By the Markov property applied after the first step of the random walk we naturally get the following equation for \( n \geq 1 \)

\[
u_n = \sum_{k=1}^{\infty} \mu_k \nu_{n-k} \quad \text{for } n \geq 1.
\]

Let \( \lambda \leq \Lambda \) respectively be the lim inf and lim sup of the sequence \( \nu_n \). Suppose that \( \psi(n) \) is a subsequence such that \( \nu_{\psi(n)} \to \Lambda \), then we claim that for all \( i \geq 1 \) we have \( \nu_{\psi(n)-i} \to \Lambda \) as well when \( n \to \infty \). This is clearly implied by (5.7) for all values of \( i \) such that \( \mu_i > 0 \) and is later extending to all \( i \geq 1 \) by aperiodicity (Exercise). Summing (5.7) for \( n = \psi(N), \psi(N-1), ... \) and re-arranging the terms we get that

\[
u_{\psi(N)} \mu((0, \infty)) + \nu_{\psi(N)-1} \mu((1, \infty)) + \cdots + \nu_0 \mu((\psi(N), \infty)) = 1.
\]

Sending \( N \to \infty \) we get by the above remark that \( \Lambda \cdot \sum_{k=0}^{\infty} \mu((k, \infty)) \leq 1 \). This proves that \( \Lambda \leq \frac{1}{m} \) and this makes sense even if \( m = \infty \). Repeating the argument with the lim inf we get similarly that \( \lambda \geq \frac{1}{m} \) and this completes the proof of the theorem in the general case.

5.4 Extensions

5.4.1 Non increasing case

In this section we use a few results of the last chapter in order to investigate the case when \( \mu \) is not necessary supported by positive integers. We suppose now that \( \mu \) is supported by \( \mathbb{Z} \) (and not \( \mathbb{Z}_{>0} \) anymore), that its support generates \( \mathbb{Z} \) and furthermore that \( \mu \) admits a (finite and) strictly positive expectation \( 0 < m < \infty \). As above we consider the random walk \( (S) \) whose increments are i.i.d. of law \( \mu \) (which may not be strictly increasing anymore).

**Proposition 5.7.** Under the above hypotheses we have

\[
\mathbb{E} \left[ \sum_{i=0}^{\infty} 1_{S_i=n} \right] \xrightarrow{n \to \infty} \frac{1}{m}.
\]

**Proof.** The idea is to decompose the walk along the strict ascending ladder variables. Remember that \( (H_i^+)_{i \geq 0} \) and \( (T_i^+) \) are the strict ascending ladder heights and epochs. Then by the result of the preceding chapter \( (H^+) \) is a random walk with i.i.d. strictly positive increments of law \( H^+_1 \) and since \( (S) \) drifts towards \( \infty \) we deduce that \( \mathbb{E}[H_i^+] < \infty \). If we denote by \( \mathcal{H} \) the renewal
set \( \{0 = H_0^+ < H_1^+ < H_2^+ < \cdots \} \) then we can apply the result of the last section and deduce that
\[
\lim_{n \to \infty} P(n \in \mathcal{H}) = \frac{1}{E[H_1^+]}.
\]
On the other hand, we can write
\[
E \left[ \sum_{i=0}^{\infty} 1_{S_i=n} \right] = \sum_{j=0}^{\infty} \sum_{k=0}^{\infty} E \left[ 1_{H_k^+ = j} \sum_{i=T_k^+}^{T_{k+1}^+-1} 1_{S_i=n} \right].
\]
By the strong Markov property and translation invariance the last expectation which we now denote by \( \varphi(j-n) \) only depends on \( j - n \) and equal 0 as long as \( n > j \). By resuming over \( k \), the last display is also equal to
\[
E \left[ \sum_{i=0}^{\infty} 1_{S_i=n} \right] = \sum_{j=n}^{\infty} P(j \in \mathcal{H}) \varphi(n-j).
\]
Now notice that \( \sum_{k \geq 0} \varphi(k) = E[T_1^+] \) which is equal to \( E[H_1^+] / m \) by Wald’s identity. Letting \( n \to \infty \), we have from Theorem 5.1 that \( P(j \in \mathcal{H}) \to \frac{1}{E[H_1^+]} \). Hence we can use dominate convergence to finally get
\[
E \left[ \sum_{i=0}^{\infty} 1_{S_i=n} \right] \xrightarrow{n \to \infty} \frac{1}{E[H_1^+]} \times \frac{E[H_1^+]}{m} = \frac{1}{m}. \quad \square
\]

### 5.5 Continuous case

In this section we state the analog of Theorem 5.1 in the continuous case and only sketch the main difference in the proof. Let \( \mu \) be a distribution over \( \mathbb{R}_+ \) which is non-lattice. We denote by \( m \) the mean of \( \mu \). As usual let \( (S_i)_{i \geq 0} \) be a random walk with i.i.d. increments of law \( \mu \) started from 0 and set \( \mathcal{R} = \{S_0, S_1, S_2, \cdots \} \).

**Theorem 5.8 (Blackwell)**

For any \( h > 0 \) we have
\[
\lim_{t \to \infty} E \left[ \# (\mathcal{R} \cap [t, t+h]) \right] = \frac{h}{m}.
\]

The strategy of the proof of the above theorem in the case \( m < \infty \) can be modeled on Section 5.2. We first build a renewal set \( \tilde{\mathcal{R}} \) whose inter-times as i.i.d. of law \( \mu \) except for the first time \( X_0 \) whose distribution is characterized as follows:
\[
E[f(X_0)] = \frac{1}{m} \int \mu(dx) x \int_0^x ds f(s).
\]
One can then check that the law of \( \tilde{\mathcal{R}} \) is invariant under translation by any fixed time \( t > 0 \). Using this stationarity we deduce that
\[
E \left[ \# \left( \tilde{\mathcal{R}} \cap [t, t+h] \right) \right] = C \cdot h,
\]
for some constant $C \geq 0$. A argument similar to the one presented just after Theorem 5.1 using the law of large numbers shows that $C = \frac{1}{m}$. One then use a similar coupling argument to transfer the result from $\tilde{\mathcal{R}}$ to $\mathcal{R}$. In this case by Theorem 3.5 the random walk $(\Delta)$ of the last section is again recurrent. However it does not come back \textit{exactly} to 0 (because the walk is non-lattice) but it approaches 0 arbitrarily close. Hence, for any $\varepsilon > 0$ one can couple $\mathcal{R}$ and $\tilde{\mathcal{R}}$ so that for $t$ large enough their $t$-translates are the same up to a small shift of length smaller than $\varepsilon > 0$. Provided that $\varepsilon > 0$ is small enough in front of $h$ this is sufficient to deduce Theorem 5.8.

\textit{Exercise} 5.3. Turn the above sketch into a rigorous proof.

\textit{Exercise} 5.4. Extend Proposition 5.7 to the continuous case.
Part III:

Random trees and graphs

Figure 5.2: A large random plane tree with vertices of high degrees.
Chapter VI: Galton–Watson trees

In this chapter we use our knowledge on one-dimensional random walk to study random trees coding for the genealogy of a population where individuals reproduce independently of each other according to the same offspring distribution. These are the famous Galton–Watson trees.

![Figure 6.1: A large Galton–Watson tree and its contour function](image)

We refer to [16] for details. This chapter borrows a lot from [12].

6.1 Plane trees and Galton–Watson processes

6.1.1 Plane trees

Throughout this work we will use the standard formalism for plane trees as found in [22]. Let

\[ \mathcal{U} = \bigcup_{n=0}^{\infty} (\mathbb{N}^*)^n \]

where \( \mathbb{N}^* = \{1, 2, \ldots\} \) and \( (\mathbb{N}^*)^0 = \{\emptyset\} \) by convention. An element \( u \) of \( \mathcal{U} \) is thus a finite sequence of positive integers. We let \( |u| \) be the length of the word \( u \). If \( u, v \in \mathcal{U} \), \( uv \) denotes the concatenation of \( u \) and \( v \). If \( v \) is of the form \( uj \) with \( j \in \mathbb{N} \), we say that \( u \) is the parent of \( v \) or that \( v \) is a child of \( u \). More generally, if \( v \) is of the form \( uw \), for \( u, w \in \mathcal{U} \), we say that \( u \) is an ancestor of \( v \) or that \( v \) is a descendant of \( u \).
Definition 6.1. A plane tree $\tau$ is a (finite or infinite) subset of $U$ such that

1. $\emptyset \in \tau$ ($\emptyset$ is called the root of $\tau$),
2. if $v \in \tau$ and $v \neq \emptyset$, the parent of $v$ belongs to $\tau$
3. for every $u \in U$ there exists $k_u(\tau) \in \{0, 1, 2, \ldots\} \cup \{\infty\}$ such that $uj \in \tau$ if and only if $j \leq k_u(\tau)$.

![Figure 6.2: A finite plane tree.](image)

A plane tree can be seen as a graph, in which an edge links two vertices $u, v$ such that $u$ is the parent of $v$ or vice-versa. Notice that with our definition, vertices of infinite degree are allowed since $k_u$ may be infinite. When all the degrees are finite, this graph is of course a tree in the graph-theoretic sense, and has a natural embedding in the plane, in which the edges from a vertex $u$ to its children $u_1, \ldots, u k_u(\tau)$ are drawn from left to right. All the trees considered in these pages are plane trees. The integer $|\tau|$ denotes the number of vertices of $\tau$ and is called the size of $\tau$. For any vertex $u \in \tau$, we denote the shifted tree at $u$ by $\sigma_u(\tau) := \{v \in \tau : uv \in \tau\}$. If $a$ and $b$ are two vertices of $\tau$, we denote the set of vertices along the unique geodesic path going from $a$ to $b$ in $\tau$ by $[a, b]$.

Definition 6.2. The set $U$ is a plane tree where $k_u = \infty, \forall u \in U$. It is called Ulam’s tree.

6.1.2 Galton–Watson trees

Let $\mu$ be a distribution on $\{0, 1, 2, \ldots\}$ which we usually suppose to be different from $\delta_1$. Informally speaking, a Galton–Watson tree with offspring distribution $\mu$ is a random (plane) tree coding the genealogy of a population starting with one individual and where all individuals reproduce independently of each other according to the distribution $\mu$. Here is the proper definition:

Definition 6.3. Let $K_u$ for $u \in U$ be independent and identically distributed random variables of law $\mu$. We let $T$ be the random plane tree made of all $u = u_1u_2\ldots u_n \in U$ such that $u_i \leq K_{u_1\ldots u_{i-1}}$ for all $1 \leq i \leq n$. Then the law of $T$ is the $\mu$-Galton–Watson distribution.
Notice that the random tree defined above may very well be infinite.

**Exercise 6.1.** Show that the random tree \( T \) constructed above has the following branching property: Conditionally on \( k_\emptyset(T) = \ell \geq 0 \) then the \( \ell \) random trees \( \sigma_i(T) \) for \( 1 \leq i \leq \ell \) are independent and distributed as \( T \).

**Exercise 6.2.** If \( \tau_0 \) is a finite plane tree and if \( T \) is a \( \mu \)-Galton–Watson tree then
\[
P(T = \tau_0) = \prod_{u \in \tau_0} \mu_{k_u(\tau_0)}.
\]

We now link the Galton-Watson tree to the well-known Galton–Watson process. We first recall its construction. Let \((\xi_{i,j} : i \geq 0, j \geq 1)\) be i.i.d. random variables of law \( \mu \). The \( \mu \)-Galton–Watson process is defined by setting \( Z_0 = 1 \) and for \( i \geq 0 \)
\[
Z_{i+1} = \sum_{j=1}^{Z_i} \xi_{i,j}.
\]
The following is then clear from the above two constructions:

**Proposition 6.1.** If \( T \) is a \( \mu \)-Galton–Watson tree, then \( X_n = \#\{ u \in T : |u| = n \} \) has the law of a \( \mu \)-Galton–Watson process.

### 6.2 Lukasiewicz walk and direct applications

In this section we will encode (finite) trees via one-dimensional walks. This will enable us to get information on random Galton–Watson trees from our previous study of one-dimensional random walks.

#### 6.2.1 Lukasiewicz walk

The *lexicographical order* \( \prec \) on \( \mathcal{U} \) is defined as the reader may imagine: if \( u = i_1 i_2 \ldots i_k \) and \( v = j_1 j_2 \ldots j_k \) are two words of the same length then \( u \prec v \) if \( i_\ell < j_\ell \) where \( \ell \) is the first index where \( i_\ell \neq j_\ell \). To compare words of different lengths, we add to the right of the smaller word enough 0’s so that its length matches the other one and then use the above definition.

**Definition 6.4.** Let \( \tau \) be a finite plane tree, we write \( u_0, u_1, \ldots, u_{|\tau|-1} \) for its vertices listed in lexicographical order. The Lukasiewicz walk \( \mathcal{W}(\tau) = (\mathcal{W}_n(\tau), 0 \leq n \leq |\tau|) \) associated to \( \tau \) is given by \( \mathcal{W}_0(\tau) = 0 \) and for \( 0 \leq n \leq |\tau| - 1 \):
\[
\mathcal{W}_{n+1}(\tau) = \mathcal{W}_n(\tau) + k_{u_n}(\tau) - 1.
\]

In words, the Lukasiewicz walk consists in listing the vertices in lexicographical order and making a stack by adding the number of children of each vertex and subtracting one (for the current vertex). Since in any finite plane tree, the total number of children is equal to the number of vertices minus one, it should be clear that the Lukasiewicz walk which starts at 0 stays non-negative until it finishes at the first time it touches the value \(-1\). Note also that this walk (or
more precise its opposite) is skip-free in the sense of Chapter 4 since \( W_{i+1}(\tau) - W_i(\tau) \geq -1 \) for any \( 0 \leq i \leq |\tau| - 1 \). We leave the following exercise to the reader:

**Exercise 6.3.** Let \( T_f \) the set of all finite plane trees. Let \( W_f \) the set of all finite paths \((w_0, w_1, \ldots, w_n)\) which starts at \( w_0 = 0 \) and ends at \( w_n = -1 \) and such that \( w_{i+1} - w_i \geq -1 \) as well as \( w_i \geq 0 \) for any \( 0 \leq i \leq n - 1 \). Then taking the Lukasiewicz walk creates a bijection between \( T_f \) and \( W_f \).

### 6.2.2 Lukasiewicz walk of a Galton–Watson tree

As it turns out the Lukasiewicz walk associated to a \( \mu \)-Galton–Watson tree is roughly speaking a random walk:

**Proposition 6.2.** Let \( T \) be a \( \mu \)-Galton–Watson tree, and let \((S_n)_{n \geq 0}\) be a random walk with i.i.d. increments of law \( P(S_1 = k) = \mu(k + 1) \) for \( k \geq -1 \). If \( \theta_{-1} \) is the first hitting time of \(-1\) by the walk \( S \) then we have

\[
\begin{align*}
\left\{ (W_0(T), W_1(T), \ldots, W_{|T|}(T)) \right\}_{|T| < \infty} & \overset{(d)}{=} \left\{ (S_0, S_1, \ldots, S_{\theta_{-1}}) \right\}_{\theta_{-1} < \infty}.
\end{align*}
\]

**Proof.** To be more precise, in the last statement one could define the Lukasiewicz walk to be equal to \( \dagger \) (an abstract cemetery point) if \( T \) is infinite and similarly set \((S_0, S_1, \ldots, S_{\theta_{-1}}) = \dagger\) when \( \theta_{-1} = \infty \). Let \( \tau_0 \) be a finite plane tree with \( n \) vertices and denote by \((\omega_0(i) : 0 \leq i \leq n)\) its associated Lukasiewicz walk. By the definition of the \( \mu \)-Galton–Watson measure (see Exercise 6.2) we have

\[
P(T = \tau_0) = \prod_{u \in \tau_0} \mu_{ku}(\tau_0).
\]

On the other hand we can also compute

\[
P((S_i)_{0 \leq i \leq n} = (\omega_0(i))_{0 \leq i \leq n}) = \prod_{i=1}^{n} \mu_{\omega_0(i+1)-\omega_0(i)+1}.
\]
Clearly, by the construction of the Lukasiewicz walk the multiset \( \{ k_u(\tau_0) : u \in \tau_0 \} \) is equal to the multiset \( \{ \omega_0(i+1) - \omega_0(i) + 1 : 0 \leq i \leq n-1 \} \). Then the two above displays are equal and Exercise 6.3 completes the proof.

**Extinction probability.** Here is a direct application of the last result: a random walk proof of the following well-known criterion for survival of a Galton–Watson process.

**Theorem 6.3 (Extinction probability)**

Let \( \mu \) be an offspring distribution of mean \( m \geq 0 \) such that \( \mu \neq \delta_1 \). Recall that \( T \) denotes a \( \mu \)-Galton–Watson tree and \( (Z_n)_{n \geq 0} \) a \( \mu \)-Galton–Watson process. Then the probability that the tree is finite is equal to the smallest solution \( \alpha \in [0, 1] \) to the equation

\[
\alpha = \sum_{k \geq 0} \mu_k \alpha^k,
\]

(6.1)

in particular it is equal to 1 if \( m \leq 1 \).

**Proof.** The equivalence between the first two assertions is obvious by Proposition 6.1. We then use Proposition 6.2 to deduce that \( P(|T| = \infty) = P(\theta_{-1} = \infty) \). Since the walk \( S \) is non trivial (i.e. not constant), we know from Chapter 3 that the last probability is positive if and only if its drift is strictly positive i.e. if \( m > 1 \). The computation of the probability that the walks stays positive has been carried out in Proposition 4.12 and its translation in our context yields the statement.

**Exercise 6.4.** The standard proof of the last theorem is usually done as follows: Let \( g(z) = \sum_{k \geq 0} \mu_k z^k \) be the generating function of the offspring distribution \( \mu \).

1. Show that the generating function of \( Z_n \) is given by \( g \circ g \circ \cdots \circ g \) (\( n \)-fold composition).
2. Deduce that \( u_n = P(Z_n = 0) \) follows the recurrence relation \( u_0 = 1 \) and \( u_{n+1} = g(u_{n-1}) \).
3. Re-deduce Theorem 6.3.

**Remark 6.1 (A historical remark).** We usually attribute to Galton and Watson the introduction and study of the so-called Galton–Watson trees in 1873 in order to study the survival of family names among British lords. However, in their initial paper devoted to the calculation of the extinction probability they conclude hastily that the latter is a fixed point of Equation 6.1 and since 1 is always a fixed point, then the extinction is almost sure whatever the offspring distribution. Too bad. This is even more surprising since almost thirty years before, in 1845 Irénée-Jules Bienaymé considered the very same model and derived correctly the extinction probability. This is yet just another illustration of Stigler’s law of eponymy!

6.2.3 Lagrange inversion formula

The Lagrange inversion is a close formula for the coefficients of the inverse of a power series. More precisely, imagine that \( f(z) = \sum_{i \geq 0} f_i z^i \in \mathbb{C}[[z]] \) is a formal power series in the indeterminate \( z \).
(no convergence conditions are assumed) so that \( f_0 = 0 \) and \( f_1 \neq 0 \). One then would like to invert \( f \) i.e. finding a power series \( \phi \in \mathbb{C}[[z]] \) such that \( z = \phi(f(z)) = f(\phi(z)) \). In combinatorics the above equation is usually written in the “Lagrange formulation” by supposing that \( f(z) = \frac{z}{R(z)} \) with \( R(z) \in \mathbb{C}[[z]] \) with \( R(0) \neq 0 \) so that the equation becomes

\[
\phi(z) = z \cdot R(\phi(z)).
\] (6.2)

**Theorem 6.4 (Lagrange inversion formula)**

Let \( R \in \mathbb{C}[[z]] \) be a formal power series in \( z \) such that \([z^0]R \neq 0\). Then there exists a unique formal power series \( \phi \) satisfying (6.2) and we have for all \( k \geq 0 \) and all \( n \geq 1 \)

\[
[z^n](\phi(z))^k = \frac{k}{n} [z^{n-1}] \left( z^{k-1} R(z)^n \right),
\]

where \([z^n]f(z)\) is the coefficient in front of \( z^n \) in the formal power series \( f \in \mathbb{C}[[z]] \).

**Proof.** The idea is to interpret combinatorially the weights in the formal expansion \( z \cdot R(\phi(z)) \), where \( R(z) = \sum_{i \geq 0} r_i z^i \). Indeed, by expanding recursively the equation (6.2), it can be seen that the coefficient in front of \( z^n \) in \( \phi \) can be interpreted as a sum over all plane trees with \( n \) vertices where the weight of a tree \( \tau \) is given by

\[
w(\tau) = \prod_{u \in \tau} r_{ku(\tau)}.\]

Similarly for \( k \geq 1 \), the coefficient of \( z^n \) in \( \phi^k \) is the weight of forest of \( k \) trees having \( n \) vertices in total. Now, using the Lukasiewicz encoding, a forest can be encoded by a skip-free descending path with \( n \) steps and reaching \( -k \) for the first time at time \( n \) and the weight of such paths become \( w(S) = \prod_{i \geq 0} r_{S_i+1-S_{i+1}} \). By Feller’s combinatorial lemma, for a skip-free descending walk \( (S) \) of length \( n \) such that \( S_n = -k \) there are exactly \( k \) cyclic shifts so that \( n \) is the \( k \)-th strict descending ladder time. So if we partition the set of all walks of length \( n \) so that \( S_n = -k \) using the cyclic shift as an equivalence relation, we know that in each equivalence classes, the proportion of walks so that \( T_k^= \) \( n \) is \( \frac{k}{n} \) (most of the classes actually have \( n \) elements in it, but it could be the case that the subgroup of cyclic shifts fixing the walk is non-trivial and has order \( \ell | k \), in which case there are \( n/\ell \) elements in the orbit and \( k/\ell \) are such that \( T_k^\leq \) \( n \)). Since the weight \( w(.) \) is constant over all equivalence classes we deduce that:

\[
\sum_{(S) \text{ walks of length } n \text{ } \text{ } S_n = -k} w(S) = \frac{n}{k} \sum_{(S) \text{ walks of length } n \text{ } \text{ } S_n = -k \text{ and } T_k^\leq = n} w(S).
\]

It remains to notice that

\[
[z^{n-1}] \left( z^{k-1} R(z)^n \right),
\]

is exactly the weight of all paths \( (S) \) of length \( n \) such that \( S_n = -k \). \( \square \)
6.3 Probabilistic counting of trees

In this section we illustrate how to enumerate certain classes of trees using our knowledge on random walks. One underlying idea is to design a random variable which is uniformly distributed on the set we wish to count.

6.3.1 Prescribed degrees

Theorem 6.5 (Harary & Prins & Tutte (1964))

The number of plane trees with \(d_i\) vertices with \(i \geq 0\) children, and with \(n = 1 + \sum id_i = \sum d_i\) vertices is equal to

\[
\frac{(n-1)!}{d_0!d_1! \cdots d_i! \cdots}.
\]

[Comment retrouver Catalan en sommant?] Proof. Fix \(d_i, k\) and \(n\) as in the theorem. Notice that we must have \(n = 1 + \sum id_i = \sum d_i\). By the encoding of plane trees into their Lukaciewicz path it suffices to enumerate the number of paths starting from 0, ending at \(-1\) at \(n\) and with \(d_i\) steps of \(i - 1\) and which stay non-negative until time \(n - 1\). Clearly, if one removes the last assumption there are

\[
\binom{n}{d_0, \ldots, d_i, \ldots} = \frac{n!}{d_0!d_1! \cdots}
\]

such paths. If we partition those paths according to the cyclic shift equivalence relation, then by Lemma 4.3 (see Remark 4.3) we know that there each equivalence class has cardinal \(n\) and has a unique element which stays non-negative until time \(n - 1\). Hence the quantity we wanted to enumerate is equal to

\[
\frac{1}{n} \binom{n}{d_0, \ldots, d_i, \ldots} = \frac{(n-1)!}{k!} \prod_i \frac{1}{d_i!}.
\]

\[\square\]

Corollary 6.6 (Catalan’s counting). We have

\[
\#\{\text{plane trees with } n + 1 \text{ vertices}\} = \frac{1}{n+1} \binom{2n}{n}.
\]

Proof. With the same notation as in the preceding theorem, the number of trees with \(n \geq 1\) vertices is equal to

\[
\sum_{1+\sum d_i=n=\sum d_i} \frac{(n-1)!}{d_0!d_1! \cdots} = \frac{1}{n} \sum_{1+\sum d_i=n=\sum d_i} \binom{n}{d_0, d_1, \ldots} = \frac{1}{n} [z^{n-1}] (1 + z + z^2 + z^3 + \cdots)^n.
\]

Using Lagrange inversion formula (Theorem 6.4) the last quantity can be expressed as \([z^n] \phi(z)\) where \(\phi(z)\) is the formal series solution to \(\phi(z) = \frac{z}{1 - \phi(z)}\). Solving we get \(\phi(z) = \frac{1}{2} (1 - \sqrt{1 - 4z})\) and a coefficient extraction yields the desired formula.

\[\square\]
6.3.2 Uniform trees

We denote by $T_n$ the set of all plane trees with $n$ edges and by $T_n$ a uniform plane tree taken in $T_n$. As we shall see $T_n$ can be seen as a conditioned version of a Galton–Watson tree:

**Proposition 6.7.** Let $T$ be the Galton–Watson tree with geometric offspring distribution of parameter $1/2$, i.e. $\mu_k = \frac{1}{2}^{k+1}$ for $k \geq 0$. Then $T_n$ has the law of $T$ conditioned on having $n$ edges.

**Proof.** Let $\tau_0$ be a tree with $n$ edges. Then by Exercise 6.2 we have

$$\mathbb{P}(T = \tau_0) = \prod_{u \in \tau_0} 2^{-k_u(\tau)}. \quad \text{(Prop 4.8)}$$

However, it is easy to see that in a plane tree with $n$ edges we have $\sum_{u \in \tau_0} k_u(\tau_0) = |\tau_0| - 1 = n$ so that the last display is equal to $\frac{1}{2}^{4^{-n}}$. The point is that this probability does not depend on $\tau_0$ as long as it has $n$ edges. Hence, the conditional law of $T$ on $T_n$ is the uniform law.

Notice that the above proposition and its proof hold for any non trivial parameter of the geometric offspring distribution. However, we chose $1/2$ because in this case the offspring distribution is critical, i.e. it has mean 1. We can give another proof of 6.6:

**Proof.** Combining the last proposition with Proposition 6.2 and Kemperman formula yields

$$\mathbb{P}(|T| = n + 1) = \mathbb{P}(\theta_{-1} = n + 1) = \frac{1}{n + 1} \mathbb{P}(S_{n+1} = -1),$$

where $(S)$ is the random walk whose increments are distributed as $\mathbb{P}(S_1 = k) = 2^{-k-2}$ for $k \geq -1$ or equivalently as $G - 1$ where $G$ is the geometric offspring distribution of parameter $1/2$. Recall that $G$ is also the number of failures before the first success in a series of independent coin flips: this is the negative Binomial distribution with parameter $(1, 1/2)$. Hence $\mathbb{P}(S_{n+1} = -1) = \mathbb{P}(\text{Binneg}(n + 1, 1/2) = n)$ where Binneg($n, p$) is the negative Binomial distribution with parameter $(n, p)$. This distribution is explicit and we have $\mathbb{P}(\text{Binneg}(n, p) = k) = \binom{n+k-1}{n-1}p^n(1-p)^k$ which is our case reduces to

$$\frac{1}{n + 1} \mathbb{P}(S_{n+1} = -1) = \frac{1}{n + 1} \mathbb{P}(\text{Binneg}(n + 1, 1/2) = n) = \frac{1}{2}^{4^{-n}} \frac{1}{n + 1} \binom{2n}{n}. \quad \text{(Prop 4.8)}$$

By the previous proposition (and its proof) we have on the other hand

$$\mathbb{P}(|T| = n + 1) = \#\{\text{plane trees with } n + 1 \text{ vertices}\} \cdot \frac{1}{2}^{4^{-n}}.$$

The result follows by comparing the last two displays.

**Exercise 6.5.** Extend the above proof to show that the number of forest of $f \geq 1$ trees whose total number of edges is $n$ is equal to

$$\frac{f}{2n + f} \binom{2n + f}{n}.$$

**Exercise 6.6.** Give another proof of the last display using Theorem 6.4.
Theorem 6.8 (*Height of a uniform point*)

Let $T_n$ be a uniform plane tree with $n$ edges. Conditionally on $T_n$ let $\delta_n$ be a uniformly chosen vertex of $T_n$ and denote $H_n$ its height (the distance to the ancestor of $T_n$) then we have

$$\mathbb{P}(H_n = h) = \frac{2h+1}{2n+1} \binom{\frac{2n+1}{n-h}}{\frac{2n}{n}}.$$ 

In particular $H_n/\sqrt{n}$ converges towards the Rayleigh distribution with density $2x \exp(-x^2)1_{x>0}$.

**Proof.** We compute exactly the probability that the point $\delta_n$ is located at height $h \geq 0$.

If so, the tree $T_n$ is obtained from the line joining $\emptyset$ to $\delta_n$ by grafting $2h+1$ plane trees on its left and on its right. Obviously, the total number of edges of these trees must be equal to $n-h$. Using Exercise 6.5 we deduce that

$$\mathbb{P}(H_n = h) = \frac{2h+1}{2n+1} \binom{\frac{2n+1}{n-h}}{\frac{2n}{n}}.$$ 

The second item of the theorem follows after applying Stirling formula and using Exercise 4.13. $\square$

6.3.3 Poisson Galton-Watson trees and Cayley trees

In this section we focus on a different type of trees first studied by Cayley.

**Definition 6.5.** A **Cayley** is a labeled tree with $n$ vertices without any orientation nor distinguished point. In other words it is a spanning tree on $K_n$, the complete graph over $n$ vertices. See Fig. 6.4.

![Figure 6.4: A Cayley tree over \{1, 2, 3, 4, \ldots, 11\}.

Let $T$ be a Galton-Watson (plane) tree with Poisson offspring distribution of parameter 1 (in particular, the mean number of children is 1 and we are in the critical case). As above we denote by $T_n$ the random tree $T$ conditioned on having $n$ vertices.
Proposition 6.9. Consider $T_n$ and assign the labels $\{1, \ldots, n\}$ uniformly at random to the vertices of $T_n$. After forgetting the plane ordering $T_n$ this produces a Cayley tree which we denote by $\Sigma_n$. Then $\Sigma_n$ is uniformly distributed over all Cayley trees.

Proof. Let us first compute the probability that $T$ has $n$ vertices. Using the Lukaciewicz walk and the cyclic lemma we get that $\mathbb{P}(|T| = n) = \frac{1}{n} \mathbb{P}(S_n = -1)$, where $S$ is the random walk whose increments are centered distributed according to Poisson(1) $- 1$ variable. It follows that

$$\mathbb{P}(|T| = n) = \frac{1}{n} \mathbb{P}(% \text{Poisson}(n) = n - 1) = e^{-n} \frac{n^{n-2}}{(n-1)!}.$$ 

Fix a Cayley tree $t$ and let us study the possible ways to obtain $t$ by the above process. We first choose the root of the tree among the $n$ possibilities vertices. Once the origin is distinguished, there are $\prod_{u \in t} k_u!$ possible ways to give a planar orientation to the tree, where $k_u$ is the number of children of the vertex $u$ (for this we needed to distinguish the ancestor vertex). After these operations, each of the labeled, rooted, plane trees obtained appears with a probability (under the Galton–Watson measure) equal to

$$\frac{1}{n!} e^{-n} \prod_{u \in t} \frac{1}{k_u!}.$$ 

Performing the summation, the symmetry factors involving the $k_u!$ conveniently disappear and we get

$$\mathbb{P}(T_n \to t) = n \times \frac{e^{-n}}{n!} \left( e^{-n} \frac{n^{n-2}}{(n-1)!} \right)^{-1} = \frac{1}{n^{n-2}}.$$ 

Since the result of the last display does not depend on the shape of $t$, the induced law is indeed uniform over all Cayley trees and we have even proved:

Corollary 6.10 (Cayley’s formula). The total number of Cayley trees on $n$ vertices is $n^{n-2}$.

Exercise 6.7. For any $p \geq 2$ a $p$-tree is a plane tree such that the number of children of each vertex is either 0 or $p$. When $p = 2$ we speak of binary trees. In particular the number of edges of a $p$-tree must be a multiple of $p$. Show that for any $k \geq 1$ we have

$$\#\{p - \text{trees with } kp \text{ edges} \} = \frac{1}{kp + 1} \binom{kp + 1}{k},$$

in three ways: using a direct application of Theorem 6.5, using a probabilistic approach via a certain class of random Galton–Watson trees, or via Lagrange inversion’s formula Theorem 6.4.

6.4 Contour function

We finish this chapter by mentioning another more geometrical encoding of plane trees which is less convenient in the general case but very useful in the case of geometric Galton–Watson trees.
Let $\tau$ be a finite plane tree. The contour function $C_\tau$ associated with $\tau$ is heuristically obtained by recording the height of a particle that climbs the tree and makes its contour at unit speed. More formally, to define it properly one needs the definition of a corner: We view $\tau$ as embedded in the plane then a corner of a vertex in $\tau$ is an angular sector formed by two consecutive edges in clockwise order around this vertex. Note that a vertex of degree $k$ in $\tau$ has exactly $k$ corners. If $c$ is a corner of $\tau$, $\text{Ver}(c)$ denotes the vertex incident to $c$.

The corners are ordered clockwise cyclically around the tree in the so-called contour order. If $\tau$ has $n \geq 2$ vertices we index the corners by letting $(c_0, c_1, c_2, \ldots, c_{2n-3})$ be the sequence of corners visited during the contour process of $\tau$, starting from the corner $c_0$ incident to $\emptyset$ that is located to the left of the oriented edge going from $\emptyset$ to 1 in $\tau$.

Definition 6.6. Let $\tau$ be a finite plane tree with $n \geq 2$ vertices and let $(c_0, c_1, c_2, \ldots, c_{2n-3})$ be the sequence of corners visited during the contour process of $\tau$. We put $c_{2n-2} = c_0$ for notational convenience. The contour function of $\tau$ is the walk defined by

$$C_\tau(i) = |\text{Ver}(c_i)|, \quad \text{for } 0 \leq i \leq 2n - 2.$$ 

Figure 6.5: The contour function associated with a plane tree.

Clearly, the contour function of a finite plane tree is a finite non-negative walk of length $2|\tau| - 1$ which only makes $\pm 1$ jumps. Here as well, the encoding of a tree into its contour function is invertible:

Exercise 6.8. Show that taking the contour function creates a bijection between the set of all finite plane trees and the set of all non-negative finite walks with $\pm 1$ steps which start and end at 0.

Now, we give a probabilistic description of the law of the contour function of $\mathcal{T}$ when $\mathcal{T}$ is distributed as a geometric(1/2)-Galton–Watson tree (i.e. has the same law as in Section 6.3.2).

Proposition 6.11. Let $\mathcal{T}$ as above. Then its contour function $C_\mathcal{T}$ has the same law as

$$(S_0, S_1, \ldots, S_{\theta-1}),$$

where $(S)$ is a simple symmetric random walk and $\theta-1$ is the first hitting time of $-1$. 

82
Proof. Notice first that $T$ is almost surely finite by Theorem 6.3 and so all the objects considered above are well defined. Let $\tau_0$ be a plane tree with $n$ edges. We have seen in the previous proposition that $\mathbb{P}(T = \tau_0) = \frac{1}{2} 4^{-n}$. On the other hand, the contour function of $\tau_0$ has length $2n$ and the probability that the first $2n$ steps of $(S)$ coincide with this function and that $\theta_{-1} = 2n + 1$ is equal to $2^{-2n} \cdot \frac{1}{2} = \frac{1}{2} 4^{-n}$. This concludes the proof. 

Exercise 6.9. Give a new proof of Corollary 6.6 using the contour function.

Exercise 6.10. Let $T$ be a Galton–Watson tree with geometric(1/2) offspring distribution. The height of $T$ is the maximal length of one of its vertices. Prove that

$$\mathbb{P}(\text{Height}(T) \geq n) = \frac{1}{n + 1}.$$  

Additional exercises.

Exercise 6.11. Let $T$ be a Galton–Watson tree with offspring distribution $\mu$ such that $\mu(0) = 0$ and $\mu(1) \neq 1$. In particular the mean of $\mu$ is strictly larger than 1 and $T$ is almost surely infinite. The tree $T$ induces an infinite network (that we still denote by $T$) by putting conductance 1 on every edge. The goal of the exercise is to show that this tree is almost surely transient. For this we build a unit flux on this graph entering at the origin vertex (the image of the ancestor vertex) and escaping at infinity, the flux being split equally likely at each branching point. Let $\theta_n$ be the expected energy of that flux over the first $n$ generations of the tree.

1. Show that if $\sup_{n \geq 0} \mathbb{E}[\theta_n] < \infty$ then $T$ is transient.

2. Using the branching property of $T$ show that

$$\mathbb{E}[\theta_n] = \sum_{k=1}^{\infty} \mu_k k \left( \frac{1}{k^2} (\mathbb{E}[\theta_{n-1}] + 1) \right).$$

3. Conclude.

4. How would you extend the result to the case when $\mu(0) > 0$ but $\mathbb{E}[\mu] > 1$ and $T$ is conditioned to be infinite (this is an event of positive probability)?

Exercise 6.12. This exercise uses the local limit theorem (Theorem 8.6). Let $T$ be Galton–Watson tree with aperiodic offspring distribution $\mu$. We suppose that $\mu(1) \neq 1$, that it has mean 1 and finite variance. Recall that $k_2(T)$ denote the degree of the ancestor in $T$. Then for every $k \geq 1$ show that we have

$$\mathbb{P}(k_2(T) = k \mid |T| = n) \xrightarrow{n \to \infty} k \cdot \mu(k).$$

In words, the law of the degree of the ancestor in large Galton–Watson trees is given by the size-biased distribution of $\mu$. The finite variance condition is not necessary, see [1] for the most general case.
Chapter VII: Erdős–Rényi random graph

The goal of this chapter is to use the tools on random walks and Galton–Watson trees in order to study the phase transition for the component sizes in the famous model of random graph due to Erdős\(^1\) and Rényi\(^2\):

**Definition 7.1** \((G(n, p) \text{ model})\). The Erdős–Rényi random graph \(G(n, p)\) with parameters \(n \geq 1\) and \(p \in [0, 1]\) is the (distribution of a) random graph whose vertex set is \(V = \{1, 2, \ldots, n\}\) and where for each pair \(i \neq j \in V\) the edge \(i \leftrightarrow j\) is present with probability \(p\) independently of all the other pairs.

Notice that contrary to the setup of Part I, the random graph \(G(n, p)\) may be disconnected. We will see that the geometry of \(G(n, p)\) undergoes various phase transitions depending on the parameters \(n, p\).

### 7.1 Sharp threshold transitions

#### 7.1.1 History

The “random graph” model was introduced by Erdős and Rényi in 1959 who wanted to probe randomly a graph with \(n\) (labeled) vertices. Actually Definition 7.1 is not really due to Erdős and Rényi who consider a fixed number \(m \leq \binom{n}{2}\) of edges but rather to Edgar Gilbert. This random graph model has since then become ubiquitous in probability and commonly referred to as the “mean field model”. This means that the initial geometry of the model is trivial: one could permute all the vertices and get the same model. This is due to the fact that the isometry group of the underlying graph, the complete graph on \(n\) vertices \(K_n\) is the full permutation group \(\Sigma_n\). For the connoisseurs, the \(G(n, p)\) model can also be seen as a Bernoulli bond percolation model on \(K_n\).

**Exercise 7.1** (Infinite Erdős–Rényi random graph, Rado graph). \((*)\) Consider the random graph \(G\) whose vertex set is \(\mathbb{N}\) and where independently for each \(i, j \in \mathbb{N}\) the edge \(i \leftrightarrow j\) is present in the graph with probability \(1/2\). Show that almost surely two samples of this random graph are homomorphic.

---

\(^{1}\) Paul Erdős 1913-1996

\(^{2}\) Alfréd Rényi 1921-1970
Figure 7.1: A sample of $\mathcal{G}(n,p)$ when $n = 500$ and $p = \frac{2}{n}$, in the so-called supercritical regime. The dot representing the vertices have radii proportional to their degrees. We clearly see that there is a unique “giant” component in the graph and all the other components are very tiny.

Beyond its apparent simplicity the $\mathcal{G}(n,p)$ model is connected to many interesting and present-day topics in probability theory: the Brownian tree of Aldous, mixing time for transpositions dynamics, expander graphs... The rough structure of the graph $\mathcal{G}(n,p)$ is quite well understood. When $p = 0$ obviously the graph is totally disconnected. As far as vertex degrees are concerned, the situation is quite trivial by the Binomial-Poisson approximation theorem:

**Proposition 7.1.** If $n \cdot p(n) \to \lambda \in [0, \infty]$ then the vertex degree of the node 1 converges in distribution towards a Poisson random variable with mean $\lambda$.

In the following, if $(A_n)$ is an event referring to $\mathcal{G}(n,p_n)$ we write $A_n$ w.h.p. “with high probability” if $\mathbb{P}(\mathcal{G}(n, p_n) \in A_n) \to 1$ as $n \to \infty$. When we are in presence of events $A_n$ for which their apparition in $\mathcal{G}(n,p)$ depends on $p$ in a drastic way we speak of **sharp threshold phenomena**:
Definition 7.2 (Thresholds for graph properties). Let $A_n$ be an increasing graph property (i.e. adding edges to a graph only helps verifying $A_n$) for graphs on $n$ vertices. We say that $A_n$ has a threshold at $p \equiv p_n$ if for every $\alpha_n \to \infty$ we have

\[
P(G(n, p_n / \alpha_n) \to 0 \quad \text{whereas} \quad P(G(n, \alpha_n \cdot p_n) \to 1 \quad \text{as } n \to \infty).
\]

We say that $A_n$ has a sharp threshold at $p \equiv p_n$ if for every $\varepsilon > 0$ we have

\[
P(G(n, (1 - \varepsilon)p_n) \to 0 \quad \text{whereas} \quad P(G(n, (1 + \varepsilon)p_n) \to 1 \quad \text{as } n \to \infty.
\]

7.1.2 Sharp threshold for connectivity at $\log n / n$

The first natural question is about the overall connectedness of the graph, and this property turns out has a sharp threshold ruled by the presence or not of isolated vertices.

**Theorem 7.2 (Erdős–Rényi)**

Connectedness and existence of isolated vertices have both a sharp threshold at $p_n = \log n / n$.

**Proof.** We start by studying isolated vertices using the method of first and second moment. Since the degree of any single vertex in $G(n, p_n)$ follows a Bin$(n - 1, p_n)$ distribution, the first moment method shows that

\[
P(G(n, p_n) \text{ has an isolated vertex}) \leq E[# \text{isolated vertices}] = n P(\text{Bin}(n - 1, p_n) = 0) = n(1 - p_n)^{n - 1}.
\]

If $p_n \geq (1 + \varepsilon) \log n / n$ then the right-hand size clearly tends to 0 as $n \to \infty$ and this shows that $G(n, p_n)$ has no isolated vertices in this regime. If now $p_n \leq (1 - \varepsilon) \log n / n$ we deduce from the last display that $E[# \text{isolated vertices}] \to \infty$ but this is not sufficient to guarantee that $P(G(n, p_n) \text{ has an isolated vertex}) \to 1$. To do this, we use the second moment method:

**Lemma 7.3 (Second moment method).** Let $X \in \{0, 1, 2, \ldots\}$ be a non-negative integer valued random variable. Then we have

\[
P(X \geq 1) \geq \frac{E[X]^2}{E[X^2]}
\]

**One-line proof:** Use Cauchy-Schwarz $E[X]^2 = E[X1_{X > 0}]^2 \leq E[X^2]P(X > 0)$.

Using this method with $X = \# \text{isolated vertices}$, we have $E[X] = n(1 - p_n)^{n - 1}$ and

\[
E[X^2] = \sum_{1 \leq i, j \leq n} E[i \text{ and } j \text{ are isolated}] = n P(1 \text{ is isolated}) + n(n - 1) P(1 \text{ and } 2 \text{ are isolated}) = n(1 - p_n)^{n - 1} + n(n - 1)(1 - p_n)^{2n - 3}.
\]

In the regime $p_n \leq (1 - \varepsilon) \log n / n$ it is easy to see that $E[X]^2 \sim E[X^2]$ and so there are isolated vertices with high probability. To complete the proof of the theorem, one has to show that as long as there are no isolated vertices the graph is actually connected with high probability.
Indeed, if there are no isolated vertices, but if the graph is not connected, that means that there is a connected component in $G(n,p_n)$ whose size is between 2 and $n/2$. In particular, there is a maximal tree inside $G(n,p_n)$ of size in-between 2 and $n/2$. Recalling Cayley’s formula (Corollary 6.10), the expected number of such trees is given by

$$\sum_{k=2}^{[n/2]} \binom{n}{k} k^{k-2} p_n^{k-1} \left( (1 - p_n)^{n-k} \right)^k.$$

The binomial coefficient counts the number of choices of vertices, the second term counts the number of spanning trees, the third term imposes that the edges of the tree must be present and the final term accounts for the fact that the tree must be isolated; i.e. there are no edges between vertices of the tree and vertices outside of the tree. Taking $p_n = (1 + \varepsilon) \frac{\log n}{n}$ with $\varepsilon \in (0, 1)$, for $n$ large enough the last display is bounded above by

$$\sum_{k=2}^{[n/2]} \binom{n}{k} k^{k-2} p_n^{k-1} (1 - p_n)^{k(n-k)} \leq \sum_{k=2}^{[n/2]} \frac{n^k}{k!} \left( (1 + \varepsilon) \log n \right)^k \frac{k^k}{n^{k-1}} \exp \left( -k(n-k) \frac{(1 + \varepsilon) \log n}{n} \right)$$

$$\leq \sum_{n-k \geq n/2} \frac{n^k}{k!} (2 \log n)^k \exp \left( -k \frac{(1 + \varepsilon) \log n}{2} \right)$$

$$\approx \text{Stirling} \quad C_1 n \sum_{k=2}^{[n/2]} \left( \frac{2e \log n}{n^{1/2}} \right)^k \leq C_2 n \left( \frac{2e \log n}{n^{1/2}} \right)^2$$

and this tends to 0 as $n \to \infty$. This finishes the proof of the theorem.

\[ \square \]

Exercise 7.2. What about connectivity of the graph when $p_n$ is exactly equal to $\frac{\log n}{n}$?

Exercise 7.3. Show that a sharp threshold phenomenon for the event \{having diameter $\leq 2$\} at

$$p_n = \sqrt{\frac{2 \log n}{n}}.$$

As seen in the previous theorem, the global property of connectedness is actually ruled by a local property, namely the existence of isolated vertices. One can also focus on other “local observables” such existence of triangles (i.e. triplets $\{i,j,k\}$ connected to each other and not to other vertices of the graph) or more generally of a given graph $K$ as a subgraph. These properties does not necessarily exhibit sharp thresholds, but rather threshold transitions:

Exercise 7.4 (threshold function of existence of subgraph). Find the (sharp?) threshold functions for existence of a fixed subgraph $K$ inside $G(n,p)$ for $K$ ranging in:

\[ \bullet \quad \bullet \bullet \quad \bullet \bullet \bullet \bullet \bullet \]
7.1.3 Sharp threshold for the giant

Actually, if one does not demand that the graph is fully connected but only requires that a large connected component exists then one obtains another sharp threshold transition at a much smaller parameter. More precisely we will denote by $|C_1(n)|, |C_2(n)|, \ldots$ the sizes of the connected components of $\mathcal{G}(n, p_n)$ in decreasing order. The main theorem is the following:

**Theorem 7.4 (Double phase transition, Erdős & Rényi, Aldous)**

There is a sharp threshold transition for the existence of a giant connected component at $p_n = \frac{1}{n}$. More precisely, if $p = p_n = \frac{c}{n}$ then we have

- **Subcritical:** If $c < 1$ then there exists $A > 0$ depending on $c > 0$ such that w.h.p. we have $|C_1(n)| \leq A \log n$.

- **Supercritical:** If $c > 1$ then there exists $A > 0$ such that w.h.p. we have $|C_2(n)| \leq A \log n$ whereas $|C_1(n)| \sim (1 - \alpha(c)) \cdot n$ where $\alpha(c)$ is the solution in $(0, 1)$ of the equation

  \[ \alpha(c) = e^{-c(1-\alpha(c))}. \]

- **Critical:** If $c = 1$ then the vector $(n^{-2/3}|C_i(n)|)_{i \geq 1}$ converges in law in the finite dimensional sense towards a positive infinite vector.

The goal of the next sections is to prove the above result. We will actually only prove points $(i)$ and $(ii)$ and just indicate how to recover the scaling in point $(iii)$.

---

**Figure 7.2:** Illustration of the structure of components in $\mathcal{G}(n, p)$ for $n = 500$ in the subcritical regime, critical and supercritical regimes from left to right. Notice in particular that in the supercritical regime there is a unique giant component whereas in the other regime the first and second largest components are “comparable”.
7.2 Exploration process and large deviation inequality

In this section we explain the main idea below Theorem 7.4 which consists in remarking that “locally” the $G(n, c/n)$ model resembles a Poisson($c$)-Galton–Watson trees and can thus be analyzed via random walk with Poisson($c$)-1 increments.

7.2.1 Exploration process

Fix a given vertex, say 1, of $G(n, p)$. We will explore the connected component of 1 using the following algorithm. At any given time $t \geq 0$ there are three type of vertices: the untouched vertices $U_t$, the vertices totally explored $E_t$ and the vertices in the current stack $S_t$ whose neighborhoods remain to be explored. The algorithm evolves as follows:

- at time $t = 0$ we have $E = \emptyset$, the untouched vertices are $U_0 = \{2, 3, \ldots\}$ and the only vertex in the stack is 1.
- suppose $t \geq 0$ is given and such that $S_t \neq \emptyset$. We then select the vertex $x \in S_t$ with minimal label and reveal all the neighbors $y_1, \ldots, y_k$ of $x$ among $U_t$ (this could be an empty set!). We then put $U_{t+1} = U_t \setminus \{y_1, \ldots, y_k\}$, $S_{t+1} = (S_t \setminus \{x\}) \cup \{y_1, \ldots, y_k\}$, $E_{t+1} = E_t \cup \{x\}$.
- if at time $t \geq 0$ we have $S_t = \emptyset$ then the algorithm stops and outputs $E_\infty := E_t$ and $U_\infty = U_t$.

It should be clear from the above exploration that deterministically the set $E_\infty$ is precisely the connected component of 1 in $G(n, p)$. In the following we write $S_t = \#S_t - 1$, we also denote by $\tau = \tau(S) = \inf\{t \geq 0 : S_t = \emptyset\} = \inf\{t \geq 0 : S_t = -1\}$ and notice that $\#E_\infty = \tau$. When this exploration is performed on $G(n, p)$ the process

$$(\#U_t, \#S_t, \#E_t)_{t \geq 0}$$

is actually a Markov chain whose transition probabilities are described by the following proposition.

**Proposition 7.5.** Let $\mathcal{F}_t$ be the $\sigma$-field generated by the first $t \geq 0$ steps of the exploration process of 1 in $G(n, p)$. Conditionally on $\mathcal{F}_t$ and on $S_t \neq \emptyset$ the edges between vertices of $S_t$ and $U_t$ or between two vertices of $U_t$ are all independent and present with probability $p$. In particular, conditionally on $\mathcal{F}_t$ the increment $\Delta S_t = S_{t+1} - S_t$ is distributed as

$$\Delta S_t \overset{d}{=} \text{Bin}(\#U_t, p) - 1.$$ 

**Proof.** Notice that given the status of the edges and vertices revealed by time $t$, one could deterministically change the status of all the edges between $S_t$ and $U_t$ or in-between vertices.
of $\mathcal{U}_t$ and this would not have affected the exploration up to time $t$ (because these edges have not been explored by the algorithm). It is easy to see from this that those edges are indeed i.i.d. present with probability $p$. The last point of the theorem follows easily. An alternative, and more “algorithmic” way to see this is to imagine that all the edges of the graph $G(n,p)$ carry a question mark “?” which means that its status is currently unknown, present with probability $p$ and absent with probability $1−p$. When performing the exploration of the cluster of the vertex 1 we reveal the status of certain edges. The key point is to notice that since we are not allowed to use the randomness of unrevealed edges, at any (stopping) time $t$, conditionally on the past exploration, the edges which still carry “?” are independent and open/closed with probability $p/1−p$.

The key idea is then the following: When $n$ is large we can approximate the increments of $S_t$ by independent Poisson($c$)−1 random variables, at least at the beginning of the exploration when $\#\mathcal{U}_t \approx n$. When $c<1$ the mean increment of the exploration process is negative and so it finishes quickly. However, when $c>1$, there is a positive probability $\alpha(c)$, computed via Proposition 4.12, such that the “ideal” exploration process continues forever. In the finite world of $G(n,c/n)$ this translates into the fact that the vertex from which we started the exploration belongs to the infinite giant component. To turn these heuristics into real proofs the main technical tool is a large deviations inequality for the walk associate to the ideal model: Let $(S^{(n)})$ be a random walk $(S^{(n)}_t : t \geq 0)$ starting from 0 with i.i.d. increments of law Bin($n,c/n$) − 1. Notice that $(S^{(n)})$ is skip-free descending.

**Lemma 7.6** (Large deviations). Fix $c > 0$ and consider the random walk $S^{(n)}$ having Bin($n,c/n$) − 1 increments. For any $\varepsilon > 0$ there exists $c(\varepsilon) > 0$ such that for all $n \geq 1$ and all $k \geq 0$

$$\Pr(|S^{(n)}_k − (c−1)k| \geq \varepsilon k) \leq \exp(−kc(\varepsilon)).$$

**Proof.** Notice that $c−1$ is the mean of the increment of $S^{(n)}$: This is an example of a large deviation inequality where we show that the probability that a sum of i.i.d. random variables deviates linearly from its mean decays exponentially fast. A subtlety here, however, is that we seek for an estimate which is uniform in $n$ (involved in the law of the increments). We proceed as usual with an exponential Markov inequality. We start with the upper bound

$$\Pr(S^{(n)}_k − (c−1)k \geq \varepsilon k) = \Pr(e^{\theta(S^{(n)}_k − (c−1))} \geq e^{\theta\varepsilon k}) \leq \left(\mathbb{E}[e^{\theta(S^{(n)}_1 − (c−1))}]e^{−\theta\varepsilon}\right)^k,$$

for any $\theta > 0$. The Laplace transform of $S^{(n)}_1 − (c−1)$ can be evaluated explicitly and we have

$$\mathbb{E}[e^{\theta(S^{(n)}_1 − (c−1))}] = e^{-\theta c} \sum_{k=0}^{n} e^{\theta k} \binom{n}{k} \left(\frac{c}{n}\right)^k \left(1−\frac{c}{n}\right)^{n−k} = e^{-\theta c} \left(1 + (e^\theta − 1)\frac{c}{n}\right)^n \leq \exp(c(e^\theta − 1 − \theta)) \leq \exp(c\theta^2),$$

for all $\theta \in (0,1)$. Multiplying by $e^{−\theta\varepsilon}$, we can thus choose $\theta_0 \in (0,1)$ small enough so that

$$\mathbb{E}[e^{\theta_0(S^{(n)}_1 − (c−1))}] e^{−\theta_0\varepsilon} < 1$$
for all \( n \geq 1 \) and then the above exponential Markov inequality for \( \theta = \theta_0 \) yields that \( \mathbb{P}(S_k^{(n)} - (c-1)k \geq \varepsilon k) \) decays exponentially (uniformly in \( n \geq 1 \)) as \( k \to \infty \) as desired. The lower bound is similar except that we should use negative \( \theta \)'s.

\[ \square \]

### 7.2.2 Upper bounds: subcritical and critical cases

**Subcritical case.** Suppose first that \( c < 1 \). We start the exploration of a given vertex in \( G(n, c/n) \) and use the above notation. Since we always have \( \#U_t \leq n \) we deduce that the increments of \( S_t \) are stochastically dominated by independent Bin\((n, c/n)\) variables and so that the size of the connected component of any given vertex is stochastically dominated by \( \tau(n) - 1 \) where \( \tau(n) \) is the hitting time of \(-1\) by the random walk \((S_t^{(n)} : t \geq 0)\) starting from 0 with i.i.d. increments of law Bin\((n, c/n) - 1\).

Since \( c < 1 \) using the above lemma we have for all \( A \geq 1 \)

\[
\mathbb{P}(\tau(n) > A) \leq \mathbb{P}(S(n) \geq 0) \leq \exp(-\eta A),
\]

for some \( \eta > 0 \). Taking \( A = \frac{2}{\eta} \log n \) we deduce using the union bound that

\[
\mathbb{P}(|C_1(n)| \geq \frac{2}{\eta} \log n) \leq n \mathbb{P}(\tau(n) \geq \frac{2}{\eta} \log n) \leq n \exp(-2\log n) \to 0.
\]

**Critical case.** The same strategy can be used in the critical case \( c = 1 \) (together with a little size-biasing trick). In this case the hitting time of 0 by \( S^{(n)} \) can be evaluate via Kemperman’s formula Proposition 4.8 and an explicit computation:

\[
\mathbb{P}(\tau(n) = k) = \frac{1}{k} \mathbb{P}(\text{Bin}(k \cdot n, c/n) = k - 1)
= \frac{1}{k} \left( \frac{nk}{k - 1} \right) \left( \frac{1}{n} \right)^{k-1} \left( 1 - \frac{1}{n} \right)^{nk-(k-1)}
\leq \frac{1}{k} \frac{nk}{(k - 1)!} e^{-(k-1)} \leq Ck^{-3/2},
\]

for some universal constant \( C > 0 \) as long a \( n \) is large enough. In particular \( \mathbb{P}(\tau(n) > k) \) decays at least as \( k^{-1/2} \) for \( k \) large. Now pick (independently of \( G(n, 1/n) \)) a vertex \( U_n \) uniformly in \( \{1, 2, \ldots, n\} \). Since the size of the cluster of \( U_n \) is stochastically dominated by \( \tau(n) \) we have

\[
\mathbb{P}(\tau(n) \geq A) \geq \mathbb{P}(\#\text{Cluster}(U_n) \geq A) \geq \mathbb{P}(|C_1(n)| \geq A \text{ and } U_n \in C_1(n)) \geq \frac{A}{n} \mathbb{P}(|C_1(n)| \geq A).
\]

Now taking \( A = \lambda n^{2/3} \) and using the above asymptotic for \( \mathbb{P}(\tau \geq A) \) yields

\[
\mathbb{P}(|C_1(n)| \geq \lambda n^{2/3}) = O(\lambda^{-1/3}),
\]

which already gives the good order of magnitude of the largest cluster in \( G(n, 1/n) \). Getting the full distributional convergence of \( (n^{-2/3}|C_i(n)|)_{i \geq 1} \) requires to understand in much more details the exploration process and this exits the scope of these lecture notes.
7.3 Supercritical case

We suppose now that \( c > 1 \). The random walk \((S^{(n)})\) starting from 0 and whose increments are given by independent \( \text{Bin}(n, c/n) - 1 \) variables then drifts towards \( +\infty \). According to Proposition 4.12, the probability \( 1 - \alpha_n(c) \) that \( S^{(n)} \) stays non-negative for all time is solution to

\[
\alpha_n(c) = \sum_{k=-1}^{\infty} (\alpha_n(c))^{k+1} \mathbb{P}(\text{Bin}(n, c/n) - 1 = k).
\]

Since \( \text{Bin}(n, c/n) \to \text{Poi}(c) \) it is easy to check that \( \alpha_n(c) \) converges towards \( \alpha(c) \) which is solution to

\[
\alpha(c) = \sum_{k=-1}^{\infty} (\alpha(c))^{k+1} \mathbb{P}(\text{Poi}(c) = k + 1) = e^{-c(1-\alpha(c))},
\]

so that \( 1 - \alpha(c) \) is the probability that a random walk starting from 0 with i.i.d. \( \text{Poisson}(c)-1 \) increments stays non-negative for ever. We recover here the value \( \alpha(c) \) appearing in Theorem 7.4. Notice in passing that \( \alpha(c) \) is continuous in \( c \). For the supercritical case, the fact that we have explored vertices decreases the “super criticality” along the exploration and so we need some care. However, since \( c > 1 \), as long as \( \#U_t \geq n - m \) the increments of \( \#E_t \) are stochastically dominated by \( \text{Bin}(n - m, \frac{c}{n}) \) whose mean is larger than 1, at least when \( m = o(n) \). We will thus explore the cluster of a given vertex in \( G(n, c/n) \) but we freeze the exploration either at its death time \( \theta(n) \) or after \( n^{2/3} \) exploration steps (which we assume to be integer to simplify our notation).

**Lemma 7.7.** For any \( \varepsilon > 0 \), for all \( n \) large enough we can couple (i.e. realizing on the same probability space)

- the exploration process \((S_t)_{0 \leq t \leq \tau}\),
- a random walk \((S^{(n)}_t)_{t \geq 0}\) starting from 0 with i.i.d. increments of law \( \text{Bin}(n, c/n) - 1 \),
- a random walk \((\tilde{S}^{(n)}_t)_{t \geq 0}\) starting from 0 with i.i.d. increments of law \( \text{Bin}(n(1-\varepsilon), c/n) - 1 \),

such that with probability at least \( 1 - o(1/n) \) we have

\[
\tilde{S}^{(n)}_t \leq S_t \leq S^{(n)}_t, \quad \text{for every } 0 \leq t \leq \tau \wedge n^{2/3}.
\]

**Proof.** The upper coupling of \( S \) and \( S^{(n)} \) is already used in the last section and follows from the fact that the increments of \( S \) are always stochastically dominated by those of \( S^{(n)} \). In passing, we can use the large deviations inequalities of Lemma 7.6 to deduce that the probability that \( S^{(n)} \), and a fortiori \( S \), exceeds the level \( \varepsilon n \) before time \( n^{2/3} \) is of probability \( \exp(-\delta n^{2/3}) = o(1/n) \). On this event, we can use the remark made before the lemma and deduce that the increments of \( S \) dominates stochastically those of \( \tilde{S}^{(n)} \). This yields the desired coupling. \( \square \)

**Corollary 7.8.** Fix \( c > 1 \). There exist \( A, \eta > 0 \), such that during the exploration of the cluster of a given vertex in \( G(n, c/n) \), with a probability \( 1 - o(1/n) \) we are in one of the following two alternatives:
Figure 7.3: Illustration of the sandwich coupling of the exploration in-between two random walks.

- Either the exploration process stops before time $A \log n$, and thus the size of the cluster is less than $A \log n$,
- Or the exploration process runs for at least $n^{2/3}$ steps and the current stack contains at least $\eta n^{2/3}$ vertices to be explored.

Asymptotically, the probability of the second alternative is $1 - \alpha(c)$.

Proof. We use the coupling of the preceding lemma with $\varepsilon > 0$ small enough so that $(1 - \varepsilon)c > 1 + \frac{c - 1}{2} > 1$. On the event on which the size of the cluster $\tau$, which is equal to the death time of the exploration, is equal to $k \leq n^{2/3}$ we must have $\tilde{S}_k(n) \leq -1 \leq 0$ and so

$$
\mathbb{P}(A \log n \leq \tau \leq n^{2/3}) \leq \sum_{k = A \log n}^{n^{2/3}} \mathbb{P}(\tilde{S}_k(n) \leq 0).
$$

Since we assume that the mean drift $(1 - \varepsilon)c - 1$ of $\tilde{S}(n)$ is positive, we can then apply the large deviation estimate of Lemma 7.6 to see that the right-hand side of the last display is bounded above by $n^{2/3} e^{-\delta A \log n}$ for some $\delta > 0$. Picking $A > 0$ large enough we can make the last probability $o(1/n)$ establishing the desired dichotomy. The fact that on the second case $S_{n^{2/3}} \geq \tilde{S}(n)_{n^{2/3}} \geq \frac{c - 1}{2} n^{2/3}$ with probability $1 - o(1/n)$ again follows from large deviations inequalities on $\tilde{S}(n)_{n^{2/3}}$ and by our choice of $\varepsilon$.

Using the coupling of $S, S(n)$ and $\tilde{S}(n)$ we see that the probability to be in the second case of the exploration implies that $S(n)$ is non-negative until time $n^{2/3}$ and is implied by the fact that $\tilde{S}(n)$ is non-negative until time $n^{2/3}$. It is easy to see that both these probabilities are very close when $n \to \infty$ to the probabilities that the respective walks with increments $\text{Bin}(n, c/n) - 1$ and
Bin\((1 - \varepsilon)n, c/n\) are non-negative for all time. Those probabilities converge towards \(1 - \alpha(c)\) and \(1 - \alpha((1 - \varepsilon)c)\). By continuity of \(c \mapsto \alpha(c)\) for \(c > 1\) we conclude that the probability of the last event is indeed asymptotic to \(1 - \alpha(c)\).

We can now complete the proof of Theorem 7.4 (iii):

Using the last corollary and the union bound we deduce that, w.h.p., for any \(x \in \{1, 2, \ldots, n\}\) the cluster of \(x\) in \(G(n, c/n)\) either contains less than \(A \log n\) vertices, or its exploration using the algorithm can be run for \(n^{2/3}\) yielding to at least \(\frac{c - 1}{2}n^{2/3}\) vertices in the stack to be explored. We will show that all the vertices in the second case actually belong to the same cluster in the graph, that is

\[
|\mathcal{C}_1(n)| > \frac{c - 1}{2}n^{2/3} \quad \text{and} \quad |\mathcal{C}_2(n)| < \frac{c - 1}{2}n^{2/3} \quad \text{w.h.p.} \quad (7.1)
\]

Indeed, take two vertices \(x_1, x_2\) and assume that both exploration processes reach a stack of at least \(\frac{c - 1}{2}n^{2/3}\) vertices. Either during the first steps of these explorations we discovered a vertex in common to the cluster of \(x_1\) and \(x_2\) and so they belong to the same cluster, otherwise the stacks \(S_1\) and \(S_2\) of \(n^{2/3}\) vertices related to \(x_1\) and \(x_2\) are disjoint. In this case, the Markovian property of the exploration shows that any edge between any pair of vertices in \(S_1\) and \(S_2\) is present with probability \(c/n\). The probability that there are no edge between \(S_1\) and \(S_2\) is then at most

\[
(1 - c/n) \left(\frac{c - 1}{2}\right)^2 n^{4/3} = o(n^{-2}).
\]

Performing a union bound, we get the desired claim (7.1).

It remains to show that the size of \(|\mathcal{C}_1(n)|\) or alternatively of the essentially unique cluster of size larger than \(n^{2/3}\) is of order \((1 - \alpha(c)) \cdot n\) with high probability. We already know from the second point Lemma 7.7 that a typical point \(x \in \{1, 2, \ldots, n\}\) has a cluster of size larger than \(n^{2/3}\) with probability tending to \(\alpha(c)\) which implies that

\[
\mathbb{E} \left[ \sum_{i=1}^{n} 1_{\#\text{Cluster}(i) \geq n^{2/3}} \right] \sim (1 - \alpha(c)) \cdot n, \quad \text{as } n \to \infty.
\]

To get concentration around the mean value, by Markov’s inequality (it is again a second moment method!!!) it suffices to show that

\[
\mathbb{E} \left[ \left( \sum_{i=1}^{n} 1_{\#\text{Cluster}(i) \geq n^{2/3}} \right)^2 \right] \sim \left( \mathbb{E} \left[ \sum_{i=1}^{n} 1_{\#\text{Cluster}(i) \geq n^{2/3}} \right] \right)^2,
\]

or equivalently that the probability that two points \(i, j \in \{1, 2, \ldots, n\}\) both have a cluster of size \(\geq n^{2/3}\) tends to \((1 - \alpha(c))^2\) as \(n \to \infty\). To see this, first perform the exploration of the cluster of \(i\). As above, there is a chance of order \(\alpha(c)\) that the exploration stops at \(\tau \leq A \log n\) steps. Then either the vertex \(j\) is in the explored component, which has a probability less than \(A \log n \to 0\) or it belongs to the remaining graph with conditionally on the first exploration has law \(G(n - \tau, \frac{c}{n})\). In the last case, conditionally on \(\tau \leq A \log n\) it is easy to see that \(j\) belongs to a cluster of size \(\geq n^{2/3}\) with probability asymptotic to \(1 - \alpha(c)\). This proves the claim and finishes the proof of the theorem. Of course, some details are left to the reader at that point. \(\square\)
7.4 Local convergence of Erdös–Rényi

The underlying idea driving the proof of Theorem 7.4 was that locally the graph $G(n,c/n)$ looks like a Poisson($c$)-Galton–Watson tree. The actual proof only used the exploration process and coupling with random walks but for the reader’s culture we introduce the notion of local topology to make the last statement rigorous.

7.4.1 Local topology

Imagine that we are given a metric space $(E, \delta)$ such that for any $x \in E$ and for any $r \in \{0, 1, 2, 3, \ldots\}$, there is a notion of restriction of radius $r$ in $x$ that we denote by $[x]_r \in E$.

We suppose that for any $r \geq 0$ the map $x \mapsto [x]_r$ is continuous for $\delta$ and that different restrictions of radius $r$ are compatible in the sense that $[x]_{r'} = [x]_r$ for any $r' \geq r$. We assume that for any $r \geq 0$, the set $\{[x]_r : x \in E\}$ is separable and complete for $\delta$. We also suppose that for any sequence of coherent elements $x_0, x_1, \ldots$ satisfying $[x_i]_j = x_j$ for any $0 \leq j \leq i$, there exists a unique “infinite” element $x \in E$ such that $[x]_r = x_r$, for all $r \geq 0$. \hfill (7.2)

Then we endow the space $E$ with a distance, called the local distance defined as

$$d_{\text{loc}}(x, y) = \sum_{r \geq 0} 2^{-r} \min \{1, \delta([x]_r, [y]_r)\}.$$ 

In other words, a sequence $x_n$ of elements of $E$ converges towards $x$ for the local distance if and only if for any $r \geq 0$, the sequence $[x_n]_r$ converges to $[x]_r$ for the metric $\delta$ as $n \to \infty$. Then we have the following:

**Theorem 7.9 (The local topology is Polish)**

The space $(E, d_{\text{loc}})$ is a Polish space, that is metric, separable and complete. Furthermore, a subset $A \subset E$ is pre-compact (meaning that its closure is compact) if and only if

$$\text{for every } r \geq 0 \text{ we have } \{[x]_r : x \in A\} \text{ is pre-compact.}$$

**Proof. Distance.** Let us first show that $d_{\text{loc}}$ is a distance. The symmetry is easy, as well as the triangle inequality. The separability is also easy since we suppose that if $[x]_r = [y]_r$, for all $r \geq 0$ then we have $x = y$ by (7.2). **Separation.** For any $x \in E$, we have $d_{\text{loc}}(x, [x]_r) \leq 2^{-r}$ and we supposed that the set $\{[x]_r : x \in E\}$ of all restrictions of radius $r$ is separable. Hence we make a union over $r$ of dense countable sets in $\{[x]_r : x \in E\}$ which end-up being countable and dense for $d_{\text{loc}}$. **Completeness.** If $(x_n)$ is a Cauchy sequence for $d_{\text{loc}}$ then for every $r$, the restriction $[x_n]_r$ is again Cauchy and, by completeness of $\{[x]_r : x \in E\}$, thus converges for $\delta$ to
a certain element \( y_r \in \{ [x] : x \in \mathcal{E} \} \). By continuity of \( x \mapsto [x] \), we deduce that \([y_r] = y_r\) for any \( r' \geq r \) and so by the coherence property (7.2) we can define a unique element \( y \in \mathcal{E} \) such that \( y_r = [y] \). It is then clear that \( x_n \to y \) for \( d_{\text{loc}} \). Characterization of the compacts. The condition in the theorem is clearly necessary for \( \mathcal{A} \) to be pre-compact for otherwise there exists \( r_0 \geq 0 \) and a sequence \( (x_n) \) in \( \mathcal{A} \) whose restrictions of radius \( r_0 \) are all at distance \( \varepsilon \) for each other. Such a sequence cannot admit a convergent subsequence. Conversely, a subset \( \mathcal{A} \) satisfying the condition of the theorem is easily seen to be pre-compact for \( d_{\text{loc}} \): just cover with restrictions of radius \( 2^{-r} \) centered on an \( 2^{-r} \)-net for \( \delta \) of \( \mathcal{A} \) to get a \( 2^{-r} \)-net for \( d_{\text{loc}} \).

Examples:

- We can consider the space \( (\mathcal{C}(\mathbb{R}_+, \mathbb{R}), |||\infty|||) \). This space is not Polish but satisfies the above assumptions once we put for the restriction of radius \( r \)

\[
[f]_r(x) = f(x)1_{x \leq r} + f(x)(r + 1 - x)1_{r \leq x \leq r + 1}.
\]

The local topology we create coincides with the uniform convergence of all compact sets of \( \mathbb{R}_+ \) and is now Polish.

- We can consider the space \( \mathcal{D} \) made of all possible (finite and infinite) words on a finite alphabet. This discrete space is endowed with the trivial distance \( \delta(x, y) = 1_{x \neq y} \). If \( w \) is such a word, then we can set \([w]_r\), the restriction of radius \( r \) to be the word made of the first \( r \) letters of \( w \). It is easy to see that all the conditions are satisfied.

- More generally when the space \( \mathcal{E} \) is discrete it will always be endowed with the trivial distance. Then the above process enables to put a topology on \( \mathcal{E} \) turning its rough metric into a Polish topology called the local topology.

Plane trees. In our context, let us apply the above machinery to the set \( \mathcal{T} \) of all plane trees (in the sense of Definition 6.1). If \( \tau \) is a plane tree, then for each \( r \geq 0 \) there is an obvious restriction \([\tau]_r \) consisting of the tree cut at the \( r \)th generation. Clearly all the axioms required to apply Theorem 7.9 are satisfied and thus \( (\mathcal{T}, d_{\text{loc}}) \) is a Polish space.

Pointed graphs.

Definition 7.3. A pointed graph \( g^* \) is a pair \( (g, \rho) \) where \( g \) is a (countable, locally finite, connected) graph and \( \rho \in V(g) \) is a reference vertex sometimes called the origin of the graph. Two pointed graphs \( g^* = (g, \rho) \) and \( h^* = (h, \varrho) \) are equivalent if there exists a graph homomorphism between \( g^* \) and \( h^* \) which sends \( \rho \) onto \( \varrho \) (we speak of pointed graph homomorphism).

In what follows we will obviously identify equivalent graphs and so formally work on the space of equivalence classes of pointed graphs. We will implicitly make this identification and later speak of pointed graphs (instead of equivalence classes of pointed graphs). We introduce \( \mathcal{G}^* \) the set of all (equivalence classes) of (locally finite, countable, connected) pointed graphs. If \( g^* \) is a
pointed graph, we denote by $[g^*]_r$, the restriction of radius $r$ around the origin of $g^*$ to be the (equivalence class of the) graph obtained from $g^* = (g, \rho)$ by keeping only those vertices which are at distance less than $r$ from $\rho$ and the edges between them; the resulting graph being pointed at $\rho$. The compatibility relations of the restrictions are easy to check. The fact that there are only countably many restrictions of radius $r$ is also easy to see. It requires a bit of thought to show that if $g^*_1, g^*_2, \ldots$ is a sequence of compatible graphs in the sense that $[g^*_j]_r = [g^*_r]$ for $r \leq j$ then there exists a unique (equivalence class of a) infinite pointed graph $g^*$ whose restrictions of radius $r$ is $g^*_r$ but this is also true. Hence we can apply the above procedure to endow $G^*$ with a local distance making it a Polish space. In this case, it is also easy to check that the pre-compact subset $\mathcal{A} \subseteq G^*$ are those satisfying for every $r \geq 0$ we have

$$\sup_{g^* \in \mathcal{A}} \sup_{x \in V([g^*]_r)} \deg(x) < \infty.$$  

From the previous characterization of pre-compact sets in $G^*$, it follows that for any $M > 0$, the subset of pointed graphs where the degree of any vertex is bounded by $M$ is a compact set.

**Exercise 7.5.** Compute the local limit of the following 6 sequences of pointed graphs:

![Diagram of pointed graphs](image)

### 7.4.2 Galton–Watson local limit

We can now state the local convergence of Erdős–Rényi random graphs. In $G(n, p)$, consider the random pointed graph $G^*(n, p)$ made of the cluster of the vertex 1, pointed at 1. For $c > 0$, we also denote by $T_c^*$ the random graph obtained from a Galton–Watson tree with offspring distribution Poisson($c$) (after forget the plane ordering) and pointed at the ancestor vertex.

**Theorem 7.10**

For any $c > 0$ we have the following convergence in distribution for $d_{\text{loc}}$

$$G^*(n, c/n) \xrightarrow{n \to \infty} T_c^*.$$  

Let us sketch an intuitive proof of the last result. First, the number of vertices adjacent to the vertex 1 has a Bin$(n - 1, c/n)$ distribution and the latter converges towards a Poisson($c$) distribution. Hence the 1-neighborhood of 1 in $G(n, c/n)$ looks like the 1-neighborhood of the origin in a Poisson($c$)-Galton–Watson tree. We then pass to the neighbors of 1: Each of these vertices is linked to 1 by definition and the number of other vertices to which it is linked follows a Bin$(n - 2, c/n)$ law which is also converging towards Poisson($c$). The point here is to remark that these variables are roughly independent and that it is very unlikely that when exploring
the 2-neighborhood of 1 we discover a cycle, i.e. a vertex linked to two different neighbors of 1. Hence, the 2-neighborhood of 1 looks like the 2-neighborhood of a Poisson($c$)-Galton–Watson tree. We then proceed similarly to explore the 3, 4, 5, . . . -neighborhoods of the vertex 1. Although the above sketch can be made rigorous (see [4]) and constitutes the basis of the analysis of the Erdős–Rényi model around criticality, we give another proof using the rigidity of plane tree structure.

**Proof.** Fix a pointed tree $t^* = (t, \rho)$ of height at most $r$. We will prove that
\[
P([G^*(n, c/n)]_r = t^*) \overset{n \to \infty}{\longrightarrow} P([T^*]_r = t^*). \tag{7.3}
\]
To this end it will be easier to add an additional ordering on the vertices of the tree in order to break possible symmetries. We thus consider a plane tree $t$ such that its pointed-graph version is indeed $t$ (there are generally several choices for this plane tree). We will also use the numbering of the vertices of the graph $G^*(n, c/n)$ to our advantage. We will write $[G^*(n, c/n)]_r \equiv t$ if we can map the vertices of the restriction of radius $r$ around 1 to the vertices of $[t]_r$ such that $1 \to \emptyset$ in a way which preserves the graph structure and such that the order of the “children” in $t$ coincides with the order of the vertices in $G^*(n, c/n)$. With this notation in hands we have
\[
P([G^*(n, c/n)]_r \equiv t) = N_{n,t} \cdot \prod_{u \in t; |u| < r} \left( \frac{c}{n} \right)^{k_u(t)} \cdot \left( 1 - \frac{c}{n} \right)^{n - 1 - \deg(x)}
\]
where $N_{n,t}$ is the number of ways to assign different numbers in $\{1, 2, \ldots, n\}$ to the vertices of $t$ so that the ancestor gets label 1 and so that the numbers assigned of the children of a given vertex are increasing from left to right. It is easy to see that we have the asymptotic
\[
N_{n,t} \overset{n \to \infty}{\longrightarrow} \prod_{u \in t; |u| < r} \frac{n^{k_u(t)}}{(k_u(t))!}.
\]
Combining the last displays we get that for any plane tree $t$ of height at most $r$ we have
\[
P([G^*(n, c/n)]_r \equiv t) \to P([T^*]_r = t), \quad \text{as } n \to \infty.
\]
Removing the orientation and summing over all trees yielding to a given tree neighborhood we get (7.3). Since the convergence in distribution $G^*_n \to G^*_\infty$ for the local distance is equivalent to the convergence of all the probabilities $P(G^*_n = g^*_0) \to P(G^*_\infty = g^*_0)$ for all $g^*_0 \in G^*$, it thus suffices to prove that for any pointed graph $g^*$ which is not a tree we have $\mathbb{P}([G^*(n, c/n)]_r = g^*) \to 0$ as $n \to \infty$. But this is easy since by Fatou’s lemma we have
\[
\limsup_{n \to \infty} \mathbb{P}([G^*(n, c/n)]_r \text{ is not a tree}) = 1 - \liminf_{n \to \infty} \sum_{t^*, \text{ tree}} \mathbb{P}([G^*(n, c/n)]_r = t^*) \\
\leq 1 - \sum_{t^*, \text{ tree}} \mathbb{P}([T^*]_r = t^*) \\
= 0.
\]
Figure 7.4: A list of the 1044 simple graph on 7 vertices.
In this chapter we fix a distribution $\mu$ on $\mathbb{Z}^d$ for $d \geq 1$ and as usual put

$$S_n = X_1 + \cdots + X_n,$$

where $X_1, X_2, \ldots$ are i.i.d. copies of distribution $\mu$. This random walk $(S)$ can thus be seen as a Markov chain (with homogeneous and translation invariant transitions) on $\mathbb{Z}^d$. We will usually assume that this is a “true” random walk on $\mathbb{Z}^d$ in the following sense:

**Definition 7.4.** We say that the walk is aperiodic if the Markov chain $(S)$ is irreducible and aperiodic on $\mathbb{Z}^d$.

*Figure 7.5:* A random walk in three dimensions (the color varies from blue to red as time passes) and its projections onto the three planes.
Chapter VIII: Applications of the Fourier transform

Recall that $\mu$ the step distribution of an aperiodic random walk $(S)$ on $\mathbb{Z}^d$. This chapter is devoted to the use of the Fourier transform of the measure $\mu$ defined by $\hat{\mu}(\xi) = \mathbb{E}[e^{i\xi \cdot X_1}]$ where $\xi \in \mathbb{R}^d$ in order to study the walk $(S)$. The results are based on [24, Chapter II]. Let us first recall a few basic properties of $\hat{\mu}$.

8.1 Estimates on Fourier transform

First $\hat{\mu}$ is continuous and $2\pi$ periodic in each coordinate and it characterizes the distribution $\mu$ (Lévy’s theorem). Clearly its modulus is less than or equal to 1. Actually, under our aperiodicity assumption we even have

Lemma 8.1. When $\mu$ is aperiodic we have

$$|\hat{\mu}(\xi)| < 1, \quad \text{for } \xi \in [0, 2\pi)^d \setminus 0_{\mathbb{Z}^d}.$$  

Proof. Indeed, if we have $|\hat{\mu}(\xi)| = |\mathbb{E}[e^{i\xi \cdot X_1}]| = 1$ we have also $|(\hat{\mu}(\xi))^n| = |\mathbb{E}[e^{i\xi \cdot S_n}]| = 1$. This implies by the equality case in the triangle inequality that all $e^{i\xi \cdot x}$ for $x \in \text{Supp}(\mathcal{L}(S_n))$ are (positively) aligned. Using the aperiodicity assumption, one can choose $n$ large enough so that the support of the law of $S_n$ contains 0 and the basis vectors $(1, 0, 0, \ldots) (0, 1, \ldots)$ up to $(0, 0, \ldots, 1)$. This shows that $\xi$ must have all its coordinates equal to 0 modulo $2\pi$.

Also recall that when $\mu$ has a finite first moment $m \in \mathbb{R}^d$ then we have $\hat{\mu}(\xi) = 1 + m \cdot \xi + o(\xi)$ as $\xi \to 0$. If in addition $m = 0$ and if $\mu$ has admits a second moment (i.e. $\int \mu(dx)|x|^2 < \infty$) we can define the covariance matrix $Q = \langle \mathbb{E}[X_jX_i]\rangle_{i,j \leq d}$ where $(X_i)$ represents the $i$-th coordinate of the vector $X$ which follows the law $\mu$. Then we have

$$\hat{\mu}(\xi) = 1 - \frac{\xi \cdot Q \cdot \xi}{2} + o(\xi^2). \quad (8.1)$$

Exercise 8.1. We work in the one-dimensional case to simplify:

1. Prove that if the $k$th moment $m_k$ of $\mu$ exists then $\hat{\mu}^{(k)}(0)$ exists and is equal to $i^k m_k$.

2. Prove that if $\hat{\mu}$ admits a second derivative then $m_2$ is finite.

3. Prove that $\hat{\mu}$ may admit a derivative at 0 without $m_1$ being finite (take $\mu_k = c/(k^2 \ln(k))$ for $k \geq 2$ and an appropriate $c > 0$).
Lemma 8.2. Under the aperiodicity assumption there exists $\lambda > 0$ such that

$$1 - \Re(\hat{\mu}(\xi)) \geq \lambda |\xi|^2, \quad \forall \xi \in (-\pi/2, \pi/2)^d.$$  

Proof. We use the fact that $1 - \cos(x)$ is always non-negative and larger than $cx^2$ for some $c > 0$ for $x \in [-\pi/2, \pi/2]$. For any constant $A$ we can write for small enough $\xi$

$$1 - \Re(\hat{\mu}(\xi)) = \sum_{x \in \mathbb{Z}^d} \mu_x (1 - \cos(\xi \cdot x)) \geq c \sum_{x \in \mathbb{Z}^d} \mu_x (\xi \cdot x)^2 1_{|x| < A}.$$  

The last line is obviously a non-negative quadratic form in $\xi$ depending on $A$. But as soon as $A$ is chosen large enough so that $\text{Vect}(x : |x| < A$ and $\mu_x > 0) = \mathbb{R}^d$ the last form is positive definite (we can choose such $A$ by our assumption the fact that the support of $\mu$ does not live in a strict vector space of $\mathbb{R}^d$ and so bounded from below by $c'|\xi|^2$ for some $c' > 0$. However, this is only valid in the neighborhood of the origin (depending on $A$). To extend it to all $\xi \in (-\pi/2, \pi/2)^d$ we then invoke Lemma 8.1 and possibly adapt the constant $c' > 0$. \hfill $\square$

8.2 Recurrence criterion

8.2.1 Chung-Fuchs

As it turns out, there is a necessary and sufficient condition for recurrence of the walk $(S)$ which is based on the Fourier\textsuperscript{1} transform of the law $\mu$.

Theorem 8.3 (Easy version of Chung–Fuchs)

The $d$-dimensional walk $(S)$ is recurrent if and only if we have

$$\lim_{r \uparrow 1} \int_{[-\pi, \pi]^d} d\xi \Re \left( \frac{1}{1 - r \hat{\mu}(\xi)} \right) = \infty.$$  

For clarity, we will prove the theorem in the case of one-dimensional random walk, the multi-dimensional case being mutadis mutandis the same.

Proof when $d = 1$. We suppose that $\mu$ is supported by $\mathbb{Z}$. In this setup, $(S)$ is recurrent if and only if the series $\sum_{n \geq 0} \mathbb{P}(S_n = 0)$ diverges. We can express exactly these probabilities in terms of the Fourier transform using Cauchy’s formula (the intervention of integral and series is easily justified here)

$$\mathbb{P}(S_n = 0) = \frac{1}{2\pi} \int_{-\pi}^\pi dt \mathbb{E}[e^{itS_n}] = \frac{1}{2\pi} \int_{-\pi}^\pi dt (\hat{\mu}(t))^n,$$

where we used the fact that $\mathbb{E}[e^{itS_n}] = (\hat{\mu}(t))^n$ by independence of the increments. We are lead to sum the last equality for $n \geq 0$, but before that we first multiply by $r^n$ for some $r \in [0, 1)$ in

\textsuperscript{1}Jean Baptiste Joseph Fourier 1768–1830
order to be sure that we can exchange series, expectation and integral. One gets

$$\sum_{n \geq 0} r^n \mathbb{P}(S_n = 0) = \frac{1}{2\pi} \int_{-\pi}^{\pi} dt \sum_{n \geq 0} r^n (\hat{\mu}(t))^n = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{dt}{1 - r \hat{\mu}(t)}.$$  

Since the left-hand side is real, one can take the real part in the integral. Letting $r \uparrow 1$, the first series diverges if and only if $\sum_{n \geq 0} \mathbb{P}(S_n = 0) = \infty$. This completes the proof of the theorem in the lattice case.

Actually, the Chung-Fuchs criterion is also valid for general step distribution over $\mathbb{R}^d$ (thus outside of the general setup of this chapter). Let us provide the proof so that the reader may compare them:

**Proof for non-lattice step distribution** ($d = 1$). When the walk in not lattice we may have $\mathbb{P}(S_n = 0) = 0$ for $n \geq 1$ but thanks to Definition-Proposition 3.1 one rather needs to express $\mathbb{P}(|S_n| < 1)$ in terms of the Fourier transform. This is done thanks to this lemma:

**Lemma 8.4.** Consider the function $f(x) = (1 - |x|)_+$ for $x \in \mathbb{R}$ then we have

$$\hat{f}(t) = \int_{\mathbb{R}} dx \, f(x) e^{itx} = \frac{2}{t^2} (1 - \cos(t)),$$

$$\hat{\hat{f}}(t) = \int_{\mathbb{R}} dx \, \frac{2}{x^2} (1 - \cos(x)) e^{itx} = 2\pi f(t).$$

**Proof of the lemma.** The first display is an easy calculation. The second one can be seen as a particular case of the inversion formula for Fourier transform (see Exercise 8.2).

Back to the proof of the theorem, we will use these *non-negative* functions as surrogates for the indicator function $1_{|x| < 1}$. More precisely, for some constant $c > 0$ we can write:

$$\mathbb{P}(|S_n| < 1) \leq c \mathbb{E} \left[ \hat{f}(S_n) \right]$$

$$= c \int_{\mathbb{R}} dt \mathbb{E}[e^{itS_n}] f(t)$$

$$= c \int_{\mathbb{R}} dt \hat{f}(t) (\hat{\mu}(t))^n.$$  

**Figure 8.1:** The functions $f$ and $\hat{f}$.  

103
We proceed as in the last proof and multiply by $r^n$ before summing and taking the real part to get that

$$\sum_{n \geq 0} r^n \mathbb{P}(|S_n| < 1) \leq c \int_{\mathbb{R}} dt \Re \left( \frac{f(t)}{1 - r \hat{\mu}(t)} \right) \leq c \int_{-1}^{1} dt \Re \left( \frac{1}{1 - r \hat{\mu}(t)} \right).$$

If the limit as $r \uparrow 1$ of the integral in the theorem is finite, then so is the limit of the integral of the last display and consequently the limit of the series in the left-hand side is finite. This proves transience of the walk thanks to Definition-Proposition 3.1. For the other direction we use $\hat{f}$ instead of $f$ and write

$$\mathbb{P}(|S_n| < 1) \geq \mathbb{E}[f(S_n)] = \frac{1}{2\pi} \mathbb{E} \left[ \hat{f}(S_n) \right] = \frac{1}{2\pi} \int_{\mathbb{R}} dt \mathbb{E}[e^{itS_n}] \hat{f}(t) = \frac{1}{2\pi} \int_{\mathbb{R}} dt \hat{f}(t) (\hat{\mu}(t))^n,$$

so that in the end of the day we get for $r \in [0, 1)$

$$\sum_{n \geq 0} r^n \mathbb{P}(|S_n| < 1) \geq \frac{1}{2\pi} \int_{\mathbb{R}} dt \Re \left( \frac{\hat{f}(t)}{1 - r \hat{\mu}(t)} \right) \geq c' \int_{-\pi}^{\pi} dt \Re \left( \frac{1}{1 - r \hat{\mu}(t)} \right),$$

for some $c' > 0$. It is now easy to see that if the limit as $r \to 1$ of the integral in the statement of the theorem is infinite then so is the series $\sum_{n \geq 0} \mathbb{P}(|S_n| < 1)$ implying recurrence of the walk. This completes the proof.

**Exercise 8.2 (Fourier inversion).** Let $\gamma_\sigma = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left( -\frac{x^2}{2\sigma^2} \right)$ be the standard Gaussian density with variance $\sigma^2$. We recall that $\hat{\gamma}_1(t) = \sqrt{2\pi} \gamma_1(t)$. Let $f \in L^1(\mathbb{R})$ and suppose that $\hat{f} \in L^1(\mathbb{R})$. By convoluting $f$ with $\gamma_\sigma$ as $\sigma \to 0$ show that for almost every $x$ we have

$$2\pi f(x) = \int_{\mathbb{R}} dt \ e^{-itx} \hat{f}(t).$$

In fact, there is a stronger version of Theorem 8.3 which is obtained by formally interchanging the limit and the integral in the last theorem: the random walk $(S)$ is transient or recurrent according as to whether the real part of $(1 - \hat{\mu}(t))^{-1}$ is integrable or not near 0 (we do not give the proof). Notice that in the case when the law $\mu$ is symmetric (i.e. $X \sim -X$ when $X \sim \mu$) then $\hat{\mu}$ is real valued and the monotone convergence theorem shows that the recurrence criterion of Theorem 8.3 indeed reduces to

$$\int_{0 \in \mathbb{R}^d} \frac{d\xi}{1 - \hat{\mu}(\xi)} = \infty.$$
Exercise 8.3. Let \((S_n)_{n \geq 0}\) be the simple random walk on \(\mathbb{Z}^3\), i.e. the increments are uniform among the 6 directions \((\pm 1, 0, 0), (0, \pm 1, 0)\) and \((0, 0, \pm 1)\). Show that the probability \(p\) that \(S\) never returns to the origin is equal to \(\frac{m-1}{m}\) where
\[
m = \frac{3}{(2\pi)^3} \int_0^{2\pi} d\xi_1 d\xi_2 d\xi_3 \frac{1}{3 - (\cos(\xi_1) + \cos(\xi_2) + \cos(\xi_3))}.
\]
In particular \(p \approx 0.340537 \ldots\).

Exercise 8.4. If \((S_n)_{n \geq 0}\) is a one-dimensional random walk, its symmetrized version is the random walk \((\tilde{S}_n)_{n \geq 0} = (S_n - S'_n)_{n \geq 0}\) where \((S)\) and \((S')\) are independent copies of the walk \((S)\). Using Exercise 3.1 show that if \((S)\) is recurrent then so is its symmetrized version \((\tilde{S})\) (is that an equivalence?).

### 8.2.2 Applications

Let us now give a few applications of the Chung-Fuchs theorem 8.3.

Recurrence and transience in various dimensions

**Corollary 8.5.** An aperiodic random walk on \(\mathbb{Z}^d\) is

(i) recurrent if \(d = 1\) and \(\mu\) has finite first moment and is centered,

(ii) recurrent if \(d = 2\) and \(\mu\) is centered with finite variance,

(iii) always transient if \(d \geq 3\).

**Proof.** We have already given a proof of point (i) in Chapter 3 but let us give another proof based on the Fourier criterion. In this case since \(\mu\) is centered, it is classical that we have
\[
\hat{\mu}(t) = 1 + o(t) \quad \text{as } t \to 0. \tag{8.2}
\]
Writing \(\hat{\mu}(t) = a(t) + ib(t)\) we have
\[
\Re \left( \frac{1}{1 - r \hat{\mu}(t)} \right) = \frac{1 - r a(t)}{(1 - r a(t))^2 + (r b(t))^2} \geq \frac{1 - r}{(1 - r a(t))^2 + (r b(t))^2}.
\]
Fix \(\varepsilon > 0\), using (8.2) we can find \(\delta > 0\) such that for \(t \in [0, \delta]\) we have \(|b(t)| \leq \varepsilon t\) and \(|1 - a(t)| \leq \varepsilon t\). Hence for these values of \(t\) we have \((r b(t))^2 \leq \varepsilon^2 r^2 t^2\) and \((1 - r a(t))^2 = ((1 - r) + r(1 - a(t)))^2 \leq 2(1 - r)^2 + 2\varepsilon^2 r^2 t^2\) (we used \((a + b)^2 \leq 2a^2 + 2b^2\)). Finally, using the positivity of the integrand we deduce that
\[
\int_{-\pi}^{\pi} \frac{dt}{1 - r \hat{\mu}(t)} \geq \int_0^\delta \frac{dt}{2(1 - r)^2 + 3t^2 \varepsilon^2 r^2}.
\]
The last integral is easily computed and seen to be of order \(\varepsilon^{-1}\) as \(r \uparrow 1\). Since \(\varepsilon > 0\) was arbitrary, the initial integral diverges as desired.
The proof of point (ii) is similar. First notice that \(\Re\left(\frac{1}{1-r\hat{\mu}(\xi)}\right)\) is always positive so that Fatou’s lemma implies that

\[
\int_{[-\pi,\pi]^d} d\xi \Re\left(\frac{1}{1-r\hat{\mu}(\xi)}\right) = \int_{[-\pi,\pi]^d} d\xi \liminf_{r \uparrow 1} \Re\left(\frac{1}{1-r\hat{\mu}(\xi)}\right) \leq \liminf_{r \uparrow 1} \int_{[-\pi,\pi]^d} d\xi \Re\left(\frac{1}{1-r\hat{\mu}(\xi)}\right).
\]

But because of (8.1) the integrand in the left-hand size is equivalent to \((\xi Q\xi/2)^{-1}\) which after an orthogonal change of variable is just equal to \(\|\xi\|^2_2\). Using the polar coordinates we have

\[
\int_{\text{around } 0 \in \mathbb{R}^2} \frac{d\xi}{\|\xi\|^2_2} = \int_{0^+} \frac{2\pi r dr}{r^2} = \infty,
\]

and so the limit of the integral in the Chung–Fuchs criterion is indeed infinite as desired.

For point (iii) we can write for \(0 < r < 1\) and \(\xi\) close to 0:

\[
\Re\left(\frac{1}{1-r\hat{\mu}(\xi)}\right) = \frac{\Re(1-r\hat{\mu}(\xi))}{(\Re(1-r\hat{\mu}(\xi)))^2 + (\Im(1-r\hat{\mu}(\xi)))^2} \leq \frac{1}{\Re(1-r\hat{\mu}(\xi))} \leq \frac{1}{\Re(1-\hat{\mu}(\xi))} \leq \frac{1}{\lambda|\xi|^2},
\]

where we used Lemma 8.2 for the last inequality and the fact that \(\Re(\hat{\mu}(\xi)) > 0\) when \(\xi\) is close to 0 in the third line. It remains to notice using polar coordinates that \(|x|^{-2}\) is always integrable in the neighborhood of 0 in \(\mathbb{R}^d\) for \(d \geq 3\).

\[\square\]

**Heavy-tailed random walks.** The Chung–Fuchs criterion can also be used to give an alternative proof of the transience of the heavy-tailed random walks considered in Theorem 3.7 and is central in the proof of Theorem 3.8.

**Exercise 8.5.** Reprove Theorem 3.7 using the Chung–Fuchs criterion.

### 8.3 The local central limit theorem

The central limit theorem is one of the most important theorems in probability theory and says in our context that the rescaled random walk \(S_n/\sqrt{n}\) converges in distribution towards a normal law provided that \(\mu\) is centered and has finite variance. There are many proofs of this result, the most standard being through the use of Fourier transform and Lévy’s criterion for convergence in law\(^2\). We will see below that the central limit theorem can be “desintegrated” to get a more powerful “local” version of it. The proof is again based on Fourier methods.

\(^2\) Here are a couple of other proofs: Lindeberg swapping trick, method of moments, Stein method, contraction method and Zolotarev metric. See the beautiful page by Terence Tao on this subject: https://terrytao.wordpress.com/2010/01/05/254a-notes-2-the-central-limit-theorem/
8.3.1 Local CLT

When a one-dimensional random walk with mean $m$ and variance $\sigma^2$ satisfies a central limit theorem we mean that for any $a < b$ we have

$$P\left( \frac{S_n - nm}{\sqrt{n}} \in [a, b] \right) \xrightarrow{n \to \infty} \int_a^b \frac{dx}{\sqrt{2\pi\sigma^2}} e^{-x^2/(2\sigma^2)}.$$

We say that we have a local central limit theorem if we can diminish the interval $[a, b]$ as a function of $n$ until it contains just one point of the lattice, that is if for $x \in \mathbb{Z}$ we have

$$P(S_n = x) = P\left( \frac{S_n - nm}{\sqrt{n}} \in \left[ \frac{x - nm}{\sqrt{n}}, \frac{x - nm + 1}{\sqrt{n}} \right] \right) \approx \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(x-nm)^2}{2\sigma^2}} \frac{1}{\sqrt{n}}.$$

It turns out that the necessary conditions for the central limit theorem are already sufficient to get the local central limit theorem:

**Theorem 8.6 (Local central limit theorem, Gnedenko)**

Let $\mu$ be a distribution supported on $\mathbb{Z}$, aperiodic, with mean $m \in \mathbb{R}$ and with a finite variance $\sigma^2 > 0$. Then if we denote by $\gamma_\sigma(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-x^2/(2\sigma^2)}$ the density distribution of the centered normal law of variance $\sigma^2$ then we have

$$\lim_{n \to \infty} \sup_{x \in \mathbb{Z}} n^{1/2} \left| P(S_n = x) - n^{-1/2} \gamma_\sigma \left( \frac{x - nm}{\sqrt{n}} \right) \right| = 0.$$ 

The usual central limit theorem follows from its local version. Indeed, if we consider the random variable $\tilde{S}_n = S_n + n^{-1/2}U_n$ where $U_n$ is uniform over $[0, 1]$ and independent of $S_n$. Then the local central limit theorem shows that the law of $(\tilde{S}_n - nm)/\sqrt{n}$ is absolutely continuous with respect to the Lebesgue measure on $\mathbb{R}$ whose density $f_n$ converges pointwise towards the density of $\gamma_\sigma$. Scheffe’s lemma (see Exercise 4.13) then implies that $(\tilde{S}_n - nm)/\sqrt{n}$ converges in law towards $\gamma_\sigma(dx)$ and similarly after removing the tilde.

**Proof.** The starting point is again Cauchy formula’s relating probabilities to Fourier transform:

$$P(S_n = x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} dt e^{-ixt} \mathbb{E}[e^{iS_n t}] = \frac{1}{2\pi} \int_{-\pi}^{\pi} dt e^{-ixt} (\hat{\mu}(t))^n.$$ 

Since $|\hat{\mu}(t)| < 1$ when $t \neq 0$ the main contribution of the integral comes from the integration near $0$, it is then an application of Laplace’s method. Since we want to use the series expansion of the Fourier transform near $0$ it is natural to introduce $\nu$ the image measure of $\mu$ after translation of $-m$ so that $\nu$ is centered and has finite variance: we can write $\hat{\nu}(t) = 1 - \frac{t^2}{2} + o(t^2)$ for $t$ small. The last display then becomes
\[ \mathbb{P}(S_n = x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} dt e^{-ixt} e^{inm(\hat{\nu}(t))n} \]

\[ = \frac{1}{2\pi} \int_{-\pi}^{\pi} dt e^{-ixt} e^{inm(1 - \frac{\sigma^2}{2}t^2 + o(t^2))^n} \]

\[ = \frac{1}{\sqrt{n}} \frac{1}{2\pi} \int_{-\pi\sqrt{n}}^{\pi\sqrt{n}} du e^{-iux/\sqrt{n}} e^{i\sqrt{n}mu} (1 - \frac{\sigma^2}{2n}u^2 + o(u^2/n))^n. \]

We can then approximate the last integral by

\[ \frac{1}{\sqrt{n}} \frac{1}{2\pi} \int_{-\infty}^{\infty} du e^{-iux/\sqrt{n}} e^{i\sqrt{n}mu} \gamma_{1/\sigma}(u) = \frac{1}{2\sqrt{\pi n}} \mathbb{E} \left[ \exp \left( i \left( \sqrt{nm} - \frac{x}{\sqrt{n}} \right) \frac{N}{\sigma} \right) \right], \]

where \( N \) denotes a standard normal variable. Using the identity \( \mathbb{E}[e^{itN}] = e^{-t^2/2} \) the last display is indeed equal to \( \gamma_{\sigma} \left( \frac{x - \mu n}{\sqrt{\sigma^2 n^2}} \right) / \sqrt{n} \) as desired. It remains to quantify the last approximation. The error made in the approximation is clearly bounded above by the sum of the two terms:

\[ A = \frac{1}{\sqrt{n}} \frac{1}{2\pi} \int_{|u| > \pi \sqrt{n}} du \gamma_{1/\sigma}(u), \]

\[ B = \frac{1}{\sqrt{n}} \frac{1}{2\pi} \int_{|u| < \pi \sqrt{n}} du \left| \gamma_{1/\sigma}(u) - \left( \hat{\nu} \left( \frac{u}{\sqrt{n}} \right) \right)^n \right|. \]

The first term \( A \) causes no problem since it is exponentially small (of the order of \( e^{-n} \)) hence negligible in front of \( 1/\sqrt{n} \). The second term may be further bounded above by the sum of three terms

\[ B \leq \frac{1}{\sqrt{n}} \int_{|u| < n^{1/4}} du \left| \gamma_{1/\sigma}(u) - \left( \hat{\nu} \left( \frac{u}{\sqrt{n}} \right) \right)^n \right| + \int_{n^{1/4} < |u| < \pi \sqrt{n}} du \left| \gamma_{1/\sigma}(u) \right| + \int_{n^{1/4} < |u| < \pi \sqrt{n}} du \left| \hat{\nu} \left( \frac{u}{\sqrt{n}} \right) \right|^n. \]

The first of this term is shown to be \( o(n^{-1/2}) \) using dominated convergence: in the region considered for \( u \), the integrand converges pointwise to 0; for the domination we may use the fact for \( |u| < \varepsilon \sqrt{n} \) we have by the expansion of \( \hat{\nu} \) that \( \left| \hat{\nu} \left( \frac{u}{\sqrt{n}} \right) \right|^n \leq (1 - \sigma^2 u^2/n)^n \leq e^{-\sigma^2 u^2/4}. \) The second term of the sum is handled as above and seen to be of order \( e^{-\varepsilon \sqrt{n}} \). For the third term, we bound the integrand by \( \left| \hat{\nu} \left( \frac{u}{\sqrt{n}} \right) \right|^n \leq e^{-\sigma^2 u^2/4} \) for \( |u| < \varepsilon \sqrt{n} \), as for \( \varepsilon \sqrt{n} < |u| < \pi \sqrt{n} \) we use Lemma 8.1 to bound the integrand by some \( c < 1 \). The sum of the three terms is then of negligible order compared to \( n^{-1/2} \) as desired.

The result extends to higher dimension with \textit{mutatis mutandis} the same proof. We only give the statement.

**Theorem 8.7 (Local central limit theorem, Gnedenko)**

Let \( \mu \) be distribution supported on \( \mathbb{Z}^d \), aperiodic, of mean \( m \in \mathbb{R}^d \) and with covariance
matrix $Q$. If we write

$$\gamma_Q(x) = \frac{1}{\sqrt{2\pi} \sqrt{\det(Q)}} \exp\left(-\frac{t x Q^{-1} x}{2}\right)$$

for the density of the centered Gaussian distribution with covariance $Q$ on $\mathbb{R}^d$ then we have

$$\lim_{n \to \infty} \sup_{x \in \mathbb{Z}^d} n^{-d/2} \left| \mathbb{P}(S_n = x) - n^{-d/2} \gamma_Q \left( \frac{x - nm}{\sqrt{n}} \right) \right| = 0.$$  

A closer look at the proof of the local central limit theorem shows that the main term which causes the largest discrepancy between $\mathbb{P}(S_n = x)$ and its ideal version $n^{-d/2} \gamma_Q \left( \frac{x - nm}{\sqrt{n}} \right)$ is caused by the term “B” in the last proof (and we can even replace $n^{1/4}$ by $n^\varepsilon$ with no harm). If we assume further regularity on $\mu$ we can have a better control on this term:

**Exercise 8.6.** Let $\mu$ be distribution supported on $\mathbb{Z}^d$, aperiodic, of mean $m \in \mathbb{R}^d$ and with covariance matrix $Q$. Suppose furthermore that $\mu$ admits finite third moments. Show that for any $\varepsilon > 0$ we have

$$\sup_{x \in \mathbb{Z}^d} n^{d/2} \left| \mathbb{P}(S_n = x) - n^{-d/2} \gamma_Q \left( \frac{x - nm}{\sqrt{n}} \right) \right| = O(n^{-1/2 + \varepsilon}).$$

### 8.3.2 Applications

As an application of the local central limit theorem we can prove straight away that an aperiodic random walk on $\mathbb{Z}^2$ with zero mean and finite variance is recurrent since the return probability $\mathbb{P}(S_n = (0, 0))$ decays as $1/n$ and so its series diverges. We can also use the local central limit theorem to get a precise asymptotic for the tail of the size of Galton–Watson trees in the critical case:

**Proposition 8.8.** Let $\mu$ be an offspring distribution law which is aperiodic, of mean 1 and with a finite variance $\sigma^2 \in (0, \infty)$. If $T$ is a $\mu$-Galton–Watson tree then we have

$$\mathbb{P}(|T| = n) \sim_{n \to \infty} \frac{1}{\sqrt{2\pi} \sigma^2} \cdot \frac{1}{n^{3/2}}.$$  

**Proof.** Taking the same notation as in Proposition 6.2 we have

$$\mathbb{P}(|T| = n) = \mathbb{P}(\theta_{-1} = n) = \frac{1}{n} \mathbb{P}(S_n = -1) = \frac{1}{\sqrt{2\pi} \sigma^2} \cdot \frac{1}{n^{3/2}} + o(n^{-3/2}).$$
**Exercise 8.7** (One-dimensional of the Brownian bridge). Suppose $S$ is a one-dimensional centered random walk with finite non-zero variance $\sigma^2$. Prove that for $x \in (0, 1)$ that $S_{\lfloor nx \rfloor}/\sqrt{n}$, conditioned on $S_n = 0$ converges in law towards $\mathcal{N}(0, \sigma^2 x (1 - x))$.

**Exercise 8.8** (Almost sure central limit theorem). Suppose $S$ is a one-dimensional centered random walk with finite variance $\sigma^2$. The almost sure version of the central limit theorem states that

$$
\frac{1}{\log n} \sum_{k=1}^{\lfloor nx \rfloor} \frac{1}{k} 1_{S_k \leq x \cdot \sigma \sqrt{k}} \xrightarrow{a.s.} \lim_{n \to \infty} \mathbb{P}(\mathcal{N}(0, 1) \leq x),
$$

where $\mathcal{N}(0, 1)$ is a centered standard normal random variable. Prove it (you can try weaker versions, assuming higher moments on the step distribution, or replacing almost sure convergence by convergence in probability)!
Chapter IX: Ranges and Intersections of random walks

As before we suppose that we are given an aperiodic random walk \((S)\) on \(\mathbb{Z}^d\).

9.1 Range and recurrence

**Definition 9.1.** The range of the random walk \((S)\) up to time \(n \geq 0\) is

\[ R_n = \# \{ S_0, S_1, \ldots, S_n \}. \]

9.1.1 The Kesten–Spitzer–Whitman theorem

**Theorem 9.1 (Kesten–Spitzer–Whitman)**

We have the following convergence in probability

\[ \frac{R_n}{n} \xrightarrow{(P)} \mathbb{P}(S \text{ does not come back to its starting point}). \]

In particular the range grows linearly (in probability) if and only if \((S)\) is transient.

**Proof.** We write \(c = \mathbb{P}(S_i \neq 0_{\mathbb{Z}^d} : \forall i \geq 1)\) to simplify notation. Let us first compute the expectation of the range. To do this we count each last visit to a given vertex between time 0 and time \(n\).

\[
\mathbb{E}[R_n] = \mathbb{E}\left[ \sum_{i=0}^{n} 1_{S_j \neq S_i : \forall i < j \leq n} \right]
= \sum_{i=0}^{n} \mathbb{P}(S_j \neq S_0 : \forall 0 < j \leq n - i)
\sim n \cdot \mathbb{P}(S_i \neq S_0 : \forall i \geq 1) = c \cdot n,
\]

by Cesàro\(^1\) summation. If \(c = 0\), i.e. when the walk is recurrent, we directly deduce that \(R_n/n \to 0\) in probability by Markov’s inequality. Let us suppose now that \(c > 0\) (i.e. that the walk is transient) and let us estimate the variance of the range. To simplify notation write \(\gamma_{i,n} = 1_{S_i \neq S_j : \forall i < j \leq n}\) so that we can write

\[
\mathbb{E}\left[ (R_n)^2 \right] = \sum_{0 \leq i,j \leq n} \mathbb{E}[\gamma_{i,n} \gamma_{j,n}] = 2 \sum_{0 \leq i < j \leq n} \mathbb{E}[\gamma_{i,n} \gamma_{j,n}] + O(n).
\]

\(^1\) Ernesto Cesàro (1859-1906)
We know claim that using the transience of the walk \((d \geq 3)\) one can prove that as \(0 \leq i << j << n\) we have \(\mathbb{E}[\gamma_{i,n} \gamma_{j,n}] \approx c^2\). Since we have anyway \(\mathbb{E}[(R_n)^2] \geq \mathbb{E}[R_n]^2\) one only needs one inequality: if \(0 \leq i < j \leq n\) we have

\[
\mathbb{E}[\gamma_{i,n} \gamma_{j,n}] = \mathbb{P}(S_k \neq S_0, \forall 0 < k \leq n - i \text{ and } S_k \neq S_{j-i}, \forall j - i < k \leq n - i) \\
\leq \mathbb{P}(S_k \neq S_0, \forall 0 < k \leq j - i \text{ and } S_k \neq S_{j-i}, \forall j - i < k \leq n - i) \\
\xrightarrow{\text{Markov}} \mathbb{P}(S_k \neq S_0, \forall 0 < k \leq j - i) \mathbb{P}(S_k \neq S_0, \forall 0 < k \leq n - j) (9.1)
\]

when both \(j - i\) and \(n - j\) tend to \(\infty\). By Cesàro summation again we deduce that \(\mathbb{E}[(R_n)^2]\) is asymptotically smaller than \((cn)^2\) and since it is anyway larger than \(\mathbb{E}[R_n]^2 \sim (cn)^2\) (by Cauchy–Schwarz) we deduce that \(\text{Var}(R_n) = \mathbb{E}[(R_n)^2] - \mathbb{E}[R_n]^2 = o(n^2)\). The desired convergence in probability then follows from a classical application of Markov’s inequality: for all \(\varepsilon > 0\) we have

\[
\mathbb{P}\left(\left|\frac{R_n}{n} - c\right| \geq \varepsilon\right) \leq \frac{\text{Var}(R_n)}{\varepsilon^2 n^2} \xrightarrow{n \to \infty} 0.
\]

**Remark 9.1.** There is sharper version of the last theorem where the convergence is improved to an almost sure convergence. One way to prove it is to use ergodic theory and more precisely Kingman’s subadditive ergodic theorem (which is an useful extension of the well-known theorem of Birkhoff). The key observation is to notice that the range is subadditive in the sense that

\[
\#\{S_0, \ldots, S_{n+m}\} \leq \#\{S_0, \ldots, S_n\} + \#\{S_n, \ldots, S_{n+m}\}
\]

and that \(\{S_n, \ldots, S_{n+m}\}\) is exactly the function \(R_m\) applied on the walk after shifting by the first \(n\) steps.

**9.1.2 Back on recurrence in \(d = 1\) and \(d = 2\)**

We can use Theorem 9.1 in order to give new proofs (or to re-interpret those already given) of the recurrence of centered random walk in dimension 1 and centered random walk on \(\mathbb{Z}^2\) with finite variance. Indeed, in the first case we have the strong law of large numbers, or more precisely its functional version

\[
\left(\frac{S_{[nt]}}{n}\right)_{t \geq 0} \xrightarrow{\text{p.s., } n \to \infty} 0,
\]

for the topology of uniform convergence on every compact of \(\mathbb{R}_+\). It follows that the range of the random walk is sublinear and hence the walk must be recurrent by Theorem 9.1. The second case is a bit more subtle. Suppose \((S_n)_{n \geq 0}\) is a centered random walk on \(\mathbb{Z}^2\) with finite covariance matrix \(\Sigma^2\). By Donsker’s invariance principle we have

\[
\left(\frac{S_{[nt]}}{\sqrt{n}}\right)_{t \in [0,1]} \xrightarrow{d, n \to \infty} (B_t^{(2)})_{t \in [0,1]}.
\]
where \( B^{(2)} \) is a two-dimensional Brownian motion with covariance matrix \( \Sigma^2 \). Since the range \( R_n \) during the first \( n \) steps is at most the number of points in the smallest disk centered at the origin containing all \( S_0, \ldots, S_n \) we deduce that
\[
R_n \leq \pi \cdot (\max\{\|S_k\|_2 : 0 \leq k \leq n\} + 2)^2.
\]
But the convergence towards \( B^{(2)} \) implies that \( \max\{\|S_k\|_2 : 0 \leq k \leq n\}/\sqrt{n} \) converges in distribution towards \( \chi \), the maximal \( L^2 \) norm of \( B^{(2)} \) over the time interval \([0, 1]\). Whatever this random variable is, it is easy to see that for every \( \varepsilon > 0 \) we have \( \mathbb{P}(\chi < \varepsilon) > 0 \). By Portmanteau theorem we deduce that
\[
\liminf_{n \to \infty} \mathbb{P}\left( \frac{R_n}{\sqrt{n}} < \pi\varepsilon \right) \geq \liminf_{n \to \infty} \mathbb{P}\left( \frac{\max\{\|S_k\|_2 : 0 \leq k \leq n\}}{\sqrt{n}} < \varepsilon \right) > \mathbb{P}(\chi < \varepsilon) > 0.
\]
The only way the last inequality is compatible with Theorem 9.1 is if \( \mathbb{P}(S_0 \neq S_i : \forall i \geq 1) = 0 \) i.e. if the walk is recurrent as desired.

9.1.3 The critical case \( d = 2 \)
Let us study in more details the range in the case of a simple symmetric random walk \( S^{(2)} \) on \( \mathbb{Z}^2 \), i.e. when the step distribution \( \mu \) is the uniform measure over 4 basis vectors \( \{ (\pm 1, 0), (0, \pm 1) \} \).

**Remark 9.2 (The rotation trick when \( d = 2 \)).** Let \( (S_n^{(2)})_{n \geq 0} \) be the random walk on \( \mathbb{Z}^2 \) such that its coordinates are independent and distributed as simple symmetric random walks on \( \mathbb{Z} \). Then this walk is not aperiodic since it lives on the lattice \( L^2 = \{ (x_1, \ldots, x_d) : x_1 + \cdots + x_d = 0 [2] \} \). But this lattice is easily seen to be equivalent to the initial \( \mathbb{Z}^2 \) after a dilation by \( 1/\sqrt{2} \) and a \( \pi/4 \)-rotation. In particular we deduce that
\[
\mathbb{P}(S_{2n}^{(2)} = (0, 0)) = \mathbb{P}(S_{2n}^{(2)} = (0, 0))
\]
\[
4^{-2n} \sum_{k=0}^{n} \binom{2n}{2k} \binom{2k}{k} \binom{2(n-k)}{n-k} = 4^{-2n} \binom{2n}{n} \binom{2n}{n},
\]
because for the random walk \( S \) to come back to the origin after \( 2n \) steps, it must operate exactly \( 2k \) steps along the \( x \)-direction among which \( k \) are in the positive direction and similarly \( 2(n - k) \) steps along the \( y \)-direction among which \( n - k \) in the positive direction, for some \( k \in \{0, 1, 2, \ldots, n\} \).

**Exercise 9.1.** Give a direct proof of the equality \( \sum_{k=0}^{n} \binom{2n}{2k} \binom{2k}{k} \binom{2(n-k)}{n-k} = \binom{2n}{n} \binom{2n}{n} \).

**Theorem 9.2 (Dvoretzky & Erdős)**
If \( (S_n)_{n \geq 0} \) is the simple symmetric random walk on \( \mathbb{Z}^2 \) we have
\[
\lim_{n \to \infty} \frac{\log n}{n} \cdot R_n \xrightarrow{(\mathbb{P})} \pi.
\]
Proof. The proof is similar to that of Theorem 9.1 and goes through first and second moments calculation done with more care. First when estimating the expectation of the range we need to compute

$$P(S_j \neq S_0 : \forall 0 < j \leq n)$$

hence the probability that the two-dimensional simple random walk does not come back to its starting point in the first $n$ steps. This probability tends to 0 but how slow? To simplify the exposition we write $\tau$ for the first return time to the origin by the simple symmetric two-dimensional random walk.

Lemma 9.3. We have $P(\tau > n) \sim \frac{\pi}{\log n}$ as $n \to \infty$

Proof of the lemma. By the calculation done in Remark 9.2 we have

$$P(S_{2n} = (0,0)) = 4^{-2n} \binom{2n}{n} \sim \frac{1}{\pi n}. \quad n \to \infty$$

The asymptotic can also directly be derived from the local central limit theorem (after a reduction to the aperiodic case, exercise!). Hence its generating series satisfies

$$G(x) = \sum_{n \geq 0} x^n P(S_{2n} = (0,0)) \sim -\frac{1}{\pi} \log(1-x) \text{ as } x \to 1^-.$$ 

Easy calculus exercises with formal series show that if we introduce the two other generating series

$$F(x) = \sum_{n \geq 1} x^n P(\tau = 2n) \quad \text{and} \quad H(x) = \sum_{n \geq 0} P(\tau > 2n)x^n$$

then we have the relations

$$H(x)(1-x) = (1-F(x)) \quad \text{and} \quad G(x) = 1 + F(x) + F(x)^2 + \cdots = \frac{1}{1-F(x)}.$$ 

Combining the last displays we deduce that

$$H(x) \sim \frac{-\pi}{(1-x) \log(1-x)} \quad \text{as } x \to 1^-.$$ 

Since the coefficient of $H$ are all positive and non-increasing, we are in the setup to apply Tauberian theorems to transfer estimates on $H$ into estimates on its coefficients, specifically, apply Theorem VI.13 in [11] (more precisely its easy extension in the case of non-increasing coefficients) we deduce the desired estimate

$$P(\tau > n) \sim \frac{\pi}{\log(n)}, \quad \text{as } n \to \infty.$$ 

Coming back to the proof of the theorem we deduce by adapting (9.1) that

$$\mathbb{E}[R_n] = \sum_{i=0}^{n} P(\tau > i) \sim \sum_{i=2}^{n} \frac{\pi}{\log(i)} = \pi \frac{n}{\log n}.$$
Hence it remains to estimate the variance of the range and show that $\mathbb{E}[(R_n)^2] \sim \mathbb{E}[R_n]^2$ to conclude similarly as in the case $d \geq 3$. Since we always have $\mathbb{E}[(R_n)^2] \geq \mathbb{E}[R_n]^2$ we focus on the other inequality. We again proceed as above and write

$$\mathbb{E}[(R_n)^2] = \sum_{0 \leq i, j \leq n} \mathbb{E}[\gamma_i, \gamma_j] = 2 \sum_{0 \leq i < j \leq n} \mathbb{E}[\gamma_i, \gamma_j] + O(n) \leq 2 \sum_{0 \leq i < j \leq n} \mathbb{P}(\tau > j - i)\mathbb{P}(\tau > n - j) + O(n).$$

We now exclude the terms $i, j$ such that either $|j - i| < n^{1-\varepsilon}$ or $|n - j| \leq n^{1-\varepsilon}$. They are at most $n^{2-\varepsilon/2}$ such couples (for large $n$’s) and so using Lemma 9.3 we get that

$$\mathbb{E}[(R_n)^2] \leq O(n^{2-\varepsilon/2}) + n^2 \left(\frac{\pi}{(1 - \varepsilon) \log(n)}\right)^2.$$

Hence we deduce that asymptotically we have $\mathbb{E}[(R_n)^2]/\mathbb{E}[R_n]^2 \leq 1$ and this suffices to complete the proof.

**Remark 9.3.** The convergence in probability in the last theorem can also be improved into an almost sure convergence.

We see that dimension 2 is critical for simple random walks in the sense that the behavior of the range is in-between being linear (as in the transient case when $d \geq 3$) and really sublinear as in the case $d = 1$ (with finite variance say). This is usually referred to by saying that “$d = 2$ is the critical dimension for recurrence of the simple random walk”. In other words, although the walk in recurrent in dimension 2 it is only barely recurrent.

### 9.2 Intersection of random walks

In this section we consider that the step distribution $\mu$ is aperiodic on $\mathbb{Z}^d$, is centered, and has bounded support. We then consider independent random walks trace $S^{(d)}(i) = (S_n^{(d)}(i))_{n \geq 0}$ on $\mathbb{Z}^d$ with step distribution $\mu$ which we see as random subsets of $\mathbb{Z}^d$ and ask whether these subsets intersect (i.e. whether the random walk paths intersect). For $k \geq 1$ and $d \geq 1$ we write

$$\mathcal{I}^{(d)}(k) = \sum_{x \in \mathbb{Z}^d} \prod_{i=1}^{k} 1_{x \in S^{(d)}(i)},$$

for the number of points in the intersection of the ranges. Notice that the event $\{\mathcal{I}^{(d)}(k) = \infty\}$ is invariant by any finite permutation of the increments of each of these walks, hence by Theorem 3.3 this event is independent of each $\sigma$-field generated by a fixed walk. Consequently, this event is independent of the total $\sigma$-field generated by the $k$ walks and is thus of probability 0 or 1. The main result is then:

**Theorem 9.4 (Erdős & Taylor)**

We have the following scenario according to the dimension of the ambient space:
(i) If $d \geq 5$ we have $I^{(d)}(2) < \infty$ almost surely,

(ii) If $d = 4$ we have $I^{(4)}(2) = \infty$ but $I^{(4)}(3) < \infty$ almost surely,

(iii) If $d = 3$ we have $I^{(3)}(3) = \infty$ but $I^{(3)}(4) < \infty$ almost surely,

(iv) If $d \leq 2$ for any $i \geq 2$ we have $I^{(d)}(i) = \infty$ almost surely.

\[ \begin{array}{ccccccc}
\text{dimension} & \text{1} & \text{2} & \text{3} & \text{4} & \text{5} & \text{6} \\
\text{1} & \text{5} & \text{4} & \text{3} & \text{2} & \text{1} & \\
\text{2} & \text{4} & \text{3} & \text{2} & \text{1} & & \\
\text{3} & \text{3} & \text{2} & \text{1} & & & \\
\text{4} & \text{2} & \text{1} & & & & \\
\text{5} & \text{1} & & & & & \\
\end{array} \]

\begin{itemize}

  \item \text{infinite intersection}
\end{itemize}

Figure 9.1: Illustration of the theorem

9.2.1 Estimate on Green’s function

For $x \in \mathbb{Z}^d$ we denote by $q(x)$ the probability that the random walk $S$ ever visits $x$ and $G(x)$ the expected number of such visits. Clearly we have $q(x) \leq G(x)$ but in dimension $d \geq 3$ by transience of the walk and the Markov property we have

$$G(x) \leq q(x)G(0),$$

where $G(0) < \infty$. Hence $q(x)$ and $G(x)$ are comparable up to multiplicative constants.

Lemma 9.5 (Green’s function). Let $x \in \mathbb{Z}^d$ for $d \geq 3$ and denote by $G(x)$ the expected number of visits to $x$ by $S^{(d)}$. Then there exist two constants $0 < c_1 < c_2 < \infty$ such that for all $x \in \mathbb{Z}^d$ we have

$$c_1|x|^{2-d} \leq G(x) \leq c_2|x|^{2-d}.$$

Proof. Our main tool in this proof will be the local limit theorem (notice that since $\mu$ has finite
support it automatically has finite variance). First write

\[
G(x) = \sum_{n=0}^{\infty} \mathbb{P}(S_n^{(d)} = x) = \sum_{n=0}^{\lfloor x \rfloor^2} \mathbb{P}(S_n^{(d)} = x) + \sum_{n > \lfloor x \rfloor^2} f \left( \frac{|x|}{n} \right) n^{-d/2} + o(n^{-d/2}),
\]

where \( f : \mathbb{R}^+ \to \mathbb{R}_+ \) is bounded and roughly of the form \( f(x) \approx e^{-x} \) by the local limit theorem. This already suffices for the lower bound: Considering the sum \( \sum_{n > \lfloor x \rfloor^2} f \left( \frac{|x|}{n} \right) n^{-d/2} + o(n^{-d/2}) \) yields to roughly \( |x|^2 \) values of order \( n^{-d/2} = |x|^{-d} \) hence a total larger than \( c_1 |x|^{2-d} \).

For the upper bound, we first consider the second sum in the last display: Since \( f \) is bounded and \( d \geq 3 \) this sum is at most \( C \sum_{n > |x|^2} n^{-d/2} \leq C' (|x|^2)^{1-d/2} = C' |x|^{2-d} \) as desired. It thus remains to show that the first sum is also \( O(|x|^{2-d}) \). For this we split the sum into two further sums

\[
\sum_{n=0}^{\lfloor x \rfloor^2} \mathbb{P}(S_n^{(d)} = x) = \sum_{n > \lfloor x \rfloor^2} \mathbb{P}(S_n^{(d)} = x) + \sum_{n = \lfloor x \rfloor^2} \mathbb{P}(S_n^{(d)} = x).
\]

For the second sum in the right-hand side we can use the improvement of the local central limit theorem proved in Exercise 8.6 (since \( S_1 \) is bounded it has in particular finite third moments) and bound from above

\[
\mathbb{P}(S_n^{(d)} = x) \leq C n^{-d/2} e^{-\frac{|x|^2}{Cn}} + C n^{-\frac{d+1}{2}} = C |x|^{-d} \left( \frac{|x|^2}{n} \right)^{d/2} e^{-\frac{|x|^2}{Cn}} + |x|^d n^{-\frac{d+1}{2}}
\]

bounded for \( |x|^{2-\epsilon} \leq n \leq |x|^2 \)

for some constant \( C > 0 \). Since the second sum contains roughly \( |x|^2 \) elements, it is indeed \( O(|x|^{2-d}) \) as desired. The only part left is to show that \( \sum_{n \leq |x|^{2-\epsilon}} \mathbb{P}(S_n^{(d)} = x) = O(|x|^{2-d}) \) and this will follow from the large deviation bound

\[
\mathbb{P}(S_n^{(d)} = x) \leq \mathbb{P}(|S_n^{(d)}| = |x|) = O(\exp(-|x|/\sqrt{n})).
\]

To see this we apply the same technique as in Lemma 7.6 and work coordinate by coordinate. If \( Z \) is a one-dimensional centered random walk with bounded increments then for any \( x > 0 \) we have for any \( \lambda > 0 \)

\[
\mathbb{P}(Z_n > x) = \mathbb{P}(e^{\lambda Z_n} > e^{\lambda x}) \leq \frac{\mathbb{E}[e^{\lambda Z_1}]^n}{e^{\lambda x}}.
\]

Since \( e^{\lambda Z_1} = 1 + \frac{\sigma^2}{2} \lambda^2 + o(\lambda) \) we can take \( \lambda = \frac{1}{\sqrt{n}} \) and get that that the last display is \( O(e^{-x/\sqrt{n}}) \) as desired. Performing the same estimate for the negative tail \( \mathbb{P}(Z_n < -x) \) and regrouping the coordinates of \( S \) we indeed reach the desired bound. \( \square \)
9.2.2 Proof of the Erdős–Taylor theorem

**Proof of the theorem.** There is no problem for dimension \( d \leq 2 \) since the walks are recurrent and so each \( S^{(d)}(i) \) is the whole \( \mathbb{Z}^d \). The next easy case is dimension \( d \geq 5 \) for two walks, \( d \geq 4 \) for three walks and dimension 3 for four walks, since a first moment calculation does the job. Indeed we have

\[
\mathbb{E}[I^{(d)}(k)] = \sum_{x \in \mathbb{Z}^d} (q(x))^k \approx \sum_{x \in \mathbb{Z}^d} (G(x))^k
\]

\[
\approx \sum_{x \in \mathbb{Z}^d} (|x|^{2-d})^k
\]

\[
\approx \sum_{n \geq 1} n^{(2-d)n^2-1},
\]

and the series is finite if \( k = 2 \) and \( d \geq 5 \), if \( k = 3 \) and \( d \geq 4 \) or if \( k = 4 \) and \( d \geq 3 \). It is just barely diverging for \((k, d) \in \{(2, 4), (3, 3)\}\). But to prove points (ii) and (iii) the fact that \( \mathbb{E}[I^{(d)}(k)] = \infty \) does not imply that \( I^{(d)}(k) = \infty \), if we want to provide a lower bound on a non-negative random variable (saying that it must stay close to its expectation) one needs to use the second moment method (Definition 7.3). Here, we use the fact that if \( X > 0 \) be a non-negative random variable and if \( C > 0 \) is such that \( \mathbb{E}[X]^2 \leq \mathbb{E}[X^2] \leq C \mathbb{E}[X]^2 \) then\(^2\)

\[
\mathbb{P}\left(X > \frac{\mathbb{E}[X]}{2}\right) > \frac{1}{4C}
\]

We use this method with

\[
I^{(d)}_n(k) = \sum_{x \in \mathbb{Z}^d} \prod_{j=1}^{k} 1_{S^{(d)}_i(j)=x}, \text{ for some } i \in n.
\]

Recall that \( q_n(x) \) is the probability that the point \( x \) has been visited by the walk by time \( n \). We have \( \mathbb{E}[I^{(d)}_n(k)] = \sum_{x \in \mathbb{Z}^d} q_n(x)^k \). Using the fact that \( (a+b)^k \leq 2^k (a^k + b^k) \) we can also write

\[
\mathbb{E}\left[ I^{(d)}_n(k)^2 \right] = \sum_{x, y \in \mathbb{Z}^d} \mathbb{P}(x \text{ and } y \text{ visited by all } S^{(d)}_i \text{ by time } n)
\]

\[
= \sum_{x, y \in \mathbb{Z}^d} \mathbb{P}(x \text{ and } y \text{ visited by } S^{(d)}_i \text{ by time } n)^k
\]

\[
\leq \text{Markov} \sum_{x, y \in \mathbb{Z}^d} (q_n(x)q_n(y-x) + q_n(y)q_n(x-y))^k
\]

\[
\leq 2^{k+1} \sum_{x, y \in \mathbb{Z}^d} q_n(x)q_n(y-x)^k
\]

\[
= 2^{k+1} \left( \sum_{x \in \mathbb{Z}^d} q_n(x)^k \right)^2 = 2^{k+1} \mathbb{E}[I^{(d)}_n(k)]^2.
\]

\( ^2\)this is just a simple Cauchy–Schwarz: \( \mathbb{E}[X] = \mathbb{E}[X \mathbf{1}_{X > \mathbb{E}[X]/2}] + \mathbb{E}[X \mathbf{1}_{X < \mathbb{E}[X]/2}] < \mathbb{E}[X^2]^{1/2} \mathbb{P}(X > \mathbb{E}[X]/2)^{1/2} + \mathbb{E}[X]/2. \)
We now focus on the case \((k,d) \in \{(2,4),(3,3)\}\). Since \(E[I_n^{(d)}(k)] = \infty\) we get that \(E[I_n^{(d)}(k)] \to \infty\) as \(n \to \infty\) and thanks the the above calculation and the second moment method we deduce that \(P(I_n^{(d)}(k) > E[I_n^{(d)}(k)]/2) > \frac{1}{4k^2}\) for all \(n\) and so \(P(I_n^{(d)}(k) = \infty) \geq \frac{1}{2^{k-1}}\). Since the latter probability is equal to 0 or 1 by the Hewitt-Savage law, it must be 1!  

\[\text{Remark 9.4.}\] As in the case of dimension 2 for recurrence, the dimension 4 is critical of infinite intersection of two independent random walk paths as dimension 3 is for the intersection of 3 independent random walk paths. With little more work one can for example show that the number of common intersection points within distance \(n\) is of order \(\log(n)\). Similarly, in dimension 2 the number of returns of the walk by time \(n\) is also logarithmic.

\[\text{Remark 9.5.}\] Although two random walks in dimension 2, 3 and 4 almost surely intersect, one can ask what is the probability they actually do not intersect within the first \(n\) steps. In dimension 2 and 3 this probability decays as a polynomial \(n^{-\alpha_d}\) for some \(\alpha_d > 0\). In dimension 3 the value \(\alpha_3\) is not explicitly known and is not expected to be an especially nice number whereas in dimension 2 we have \(\alpha_2 = \frac{3}{8}\). Although simple looking, the derivation of this so-called intersection exponent has required Lawler, Schramm and Werner to use a deep mixture of complex analysis and probability theory. This was celebrated by Werner’s Fields medal in 2006!

### 9.2.3 Point of increase

We now turn to a problem for which dimension one is already “critical”: existence of point of increase for the simple random walk. In the rest of this section \((S_i : i \geq 0)\) is a simple symmetric random walk on \(\mathbb{Z}\).

**Definition 9.2.** A time \(k \in \{0,1,\ldots,n\}\) is a point of increase for \(S_0,S_1,\ldots,S_n\)

\[\forall 0 \leq i \leq k, \quad S_i \leq S_k \quad \text{and} \quad \forall k \leq i \leq n, \quad S_k \leq S_i.\]

**Theorem 9.6 (Peres)**

There exists \(C > 0\) such that for all \(n \geq 1\) we have

\[P(S_0,\ldots,S_n \text{ has a point of increase}) \leq \frac{C}{\log n}.\]

**Proof.** Let us denote \(I_n\) the total number of point of increase of \(S_0,\ldots,S_n\). If we denote by \(P_n\) the event \(\{S_0 \geq 0,\ldots,S_n \geq 0\}\) and \(p_n\) its probability, then the probability that time \(k\) is a time of increase for \(S_0,\ldots,S_n\) is equal to \(p_k p_{n-k}\). Using the asymptotic \(p_k \sim c k^{-1/2}\) deduced from (4.3) we see that for some constants \(c',c'' > 0\) for all \(n \geq 1\) we have

\[E[I_n] \leq c' \sum_{k=1}^{n-1} \frac{1}{\sqrt{k(n-k)}} \leq c''.\]
Hence, the number of point of increase is bounded is expectation. To show that it is actually unlikely to have a single point of increase, we need to show that point of increase “come in pack”. More precisely, we use the simple observation:

\[
P(I_n > 0) = \frac{E[I_n]}{E[I_n | I_n > 0]},
\]

since the event \(I_n = 0\) does not contribute to the expectation of \(I_n\). Let \(A_k\) be the event that \(k \in \{0,1,\ldots,n\}\) is the first point of increase of \(S_0,\ldots,S_n\). On the event \(A_k\) notice that \(S_k - S_{k+1} - S_k,\ldots,S_n - S_k\) is path of length \(n - k\) that stays non-negative. Notice also that we could change this path for any other path that stays non-negative and we would still belong to \(A_k\). This shows that conditionally on \(A_k\), the law of \((S_{k+i} - S_k : 0 \leq i \leq n - k)\) is that of the simple random walk \(S\) conditioned on \(P_{n-k}\). Given the last display, we write

\[
E[I_n | I_n > 0] = \frac{1}{P(I_n > 0)} \sum_{k=0}^{n} E[I_n | A_k] \cdot P(A_k).
\]

Given (9.2) and since \(\sum_k P(A_k) = P(I_n > 0)\) it suffices to prove that there exists \(c > 0\) such that for all \(0 \leq k \leq n\) we have \(E(I_n | A_k) \geq c \cdot \log n\) to complete the proof of the theorem. By time-reversal we may even restrict to \(0 \leq k \leq n/2\). Writing \(m = n - k \geq n/2\) by the above remark we can compute

\[
E[I_n | A_k] = E[I_{n-k} | P_{n-k}] = E[I_m | P_m] = \frac{1}{p_m} \sum_{i=0}^{m} P(i \text{ is a p.o.i. for } S_0,\ldots,S_m \text{ and } S_j \geq 0, \forall 0 \leq j \leq m) = \frac{1}{p_m} \sum_{i=0}^{m} P(0 \leq S_j \leq S_i, \forall 0 \leq j \leq i) \cdot p_{m-i}.
\]

(9.3)

**Lemma 9.7.** There exist constant \(c_1, c_2 > 0\) such that for all \(n \geq 1\) we have

\[
\frac{c_1}{n} \leq P(S_0 \leq S_i \leq S_n : \forall 0 \leq i \leq n) \leq \frac{c_2}{n}.
\]

Given the last lemma we can finish the proof of the theorem. Indeed, using again \(p_k \sim ck^{-1/2}\) and the last lemma, we easily see that (9.3) is bounded from below by \(c' \cdot \log m \geq c \cdot \log \frac{n}{2}\) for some constant \(c > 0\) which imply the desired estimate. \(\square\)

**Proof of Lemma 9.7.** The upper bound (which has not been used in our application) follows easily from the fact that

\[
P(S_0 \leq S_i \leq S_n : \forall 0 \leq i \leq n) \leq P(S_i \geq 0 : \forall 0 \leq i < n/2) \cdot P(S_i \leq S_n : \forall n/2 < i \leq n)
\]

by duality

\[
P(S_i \geq 0 : \forall 0 \leq i < n/2)^2 = \left(\frac{p_{n/2}}{p_n}\right)^2 \sim \frac{2c}{n}
\]

for some \(c > 0\). For the lower bound, notice that the events \(A = \{S_i \geq 0 : \forall 0 \leq i \leq n\}\) and \(B = \{S_i \leq S_n : \forall 0 \leq i \leq n\}\) are positively correlated. Indeed, they are increasing events in the
sense that if A or B is realized for a path s then it realized for all the paths we can get from s by changing a minus step into a plus step. An application of the FKG inequality then shows that \( P(A \cap B) \geq P(A) \cdot P(B) \) which in our case yields

\[
P(S_0 \leq S_i \leq S_n : \forall 0 \leq i \leq n) \geq P(S_i \geq 0 : \forall 0 \leq i \leq n) \cdot P(S_i \leq S_n : \forall 0 \leq i \leq n) = p_n^2 \sim \frac{c}{n},
\]

\textbf{Bibliographical notes.} Theorem 9.6 is due to Y. Peres and the presentation here is adapted from [21, Chapter 5.2].
